Posthemorrhagic ventriculomegaly is a common consequence of germinal matrix hemorrhage. Posthemorrhagic hydrocephalus (PHH), defined as ventriculomegaly, elevated intracranial pressure, and increasing occipitofrontal head circumference is also a consequence of germinal matrix hemorrhage. PHH occurs more commonly in infants who have sustained more severe, higher-grade hemorrhages (Fig. 40-102). Interestingly, PHH occurs less commonly in preterm infants with very low birthweight and the youngest gestational ages.[53] PHH is usually a communicating hydrocephalus, secondary to an obliterative arachnoiditis over the cerebral convexities at the site of the arachnoid granulations (pacchionian villi), or at the outflow foramina of the fourth ventricle in the posterior cranial fossa. Occasionally, PHH may be a noncommunicating hydrocephalus because of obstruction of the aqueduct from intraventricular blood or blood degradation products, or subependymal scarring.

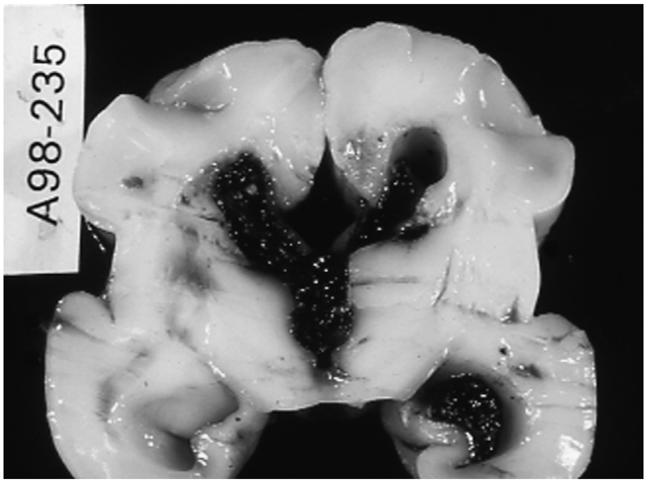

Figure 40–101. Posthemorrhagic hydrocephalus. Diffuse intraventricular hemorrhage secondary to germinal matrix bleed is seen in this coronal specimen.

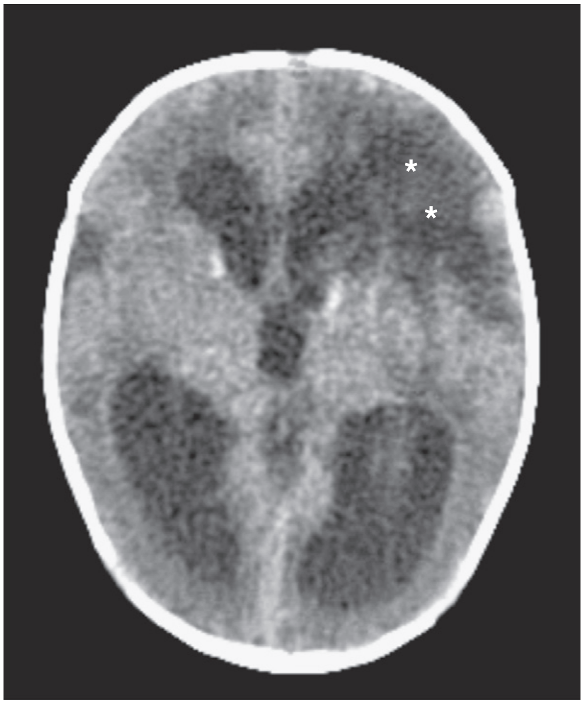

Figure 40–102. Posthemorrhagic hydrocephalus after grade IV intraventricular hemorrhage of prematurity. Computed tomography scan demonstrates enlargement of the lateral ventricles and region of left frontal encephalomalacia *(asterisks)* at the site of a parenchymal hemorrhage.

It may sometimes be difficult to differentiate posthemorrhagic ventriculomegaly from PHH. Periventricular hemorrhagic infarction may lead to encephalomalacia with relative ventriculomegaly as a consequence of volume loss. In PHH, the ventriculomegaly is often accompanied by increased head circumference and intracranial pressure. Sometimes, however, progressive hydrocephalus can develop without enlargement of the head circumference. This occurs because the immature periventricular white matter, with its paucity of myelin and excess of water, is the site of lowest resistance, allowing the ventricles to dilate before expanding the tougher dura and skull.

Treatment strategies for PHH involve a team approach. Daily neurologic examination with measurement of the OFC and weekly transfontanelle US of the brain provide useful longitudinal data to follow (Fig. 40-103). Medical therapy with acetazolamide, a noncompetitive carbonic anhydrase inhibitor, or furosemide, a loop diuretic, may provide relief, but these are usually temporizing agents. Careful monitoring of fluid and electrolyte balance is essential. Usually symptomatic hydrocephalus requires intervention with measures to remove CSF. In communicating hydrocephalus, serial lumbar punctures may be instituted. If lumbar punctures fail, or if there is noncommunicating hydrocephalus, then measures

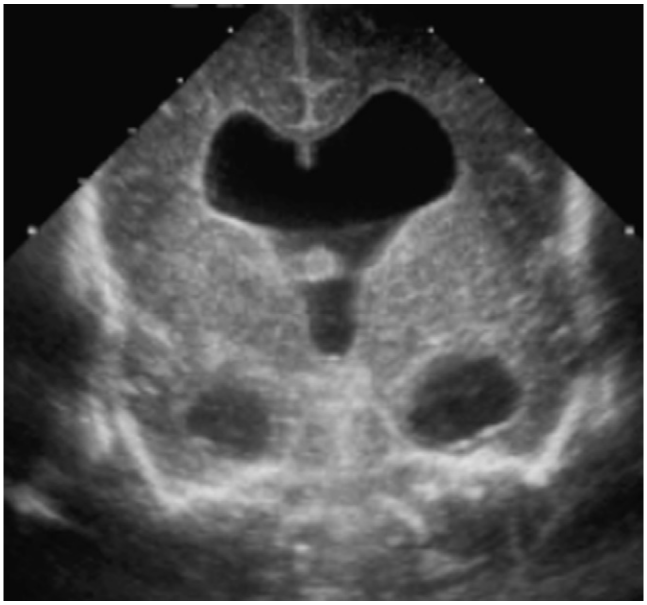

Figure 40–103. Posthemorrhagic hydrocephalus. Coronal ultrasonographic scan shows enlarged lateral ventricles and intraventricular blood.

are instituted to remove CSF from the ventricles. Such measures include ventricular taps, ventricular catheters with subgaleal reservoirs that can be tapped, ventriculosubgaleal shunts, external ventricular drains, or ventriculoperitoneal shunts. Because of the increased incidence of loculated hydrocephalus after ventricular taps, these procedures are usually reserved for infants in need of emergent CSF diversion.

POSTINFECTIOUS HYDROCEPHALUS

Communicating hydrocephalus may develop in the newborn as a consequence of arachnoidal scarring from congenital or acquired infection. Intrauterine transplacental infection (e.g., toxoplasmosis and other TORCH infections) may cause hydrocephalus due to meningoencephalitis, with pathologic changes in the subarachnoid space and cerebral parenchyma.[3,39] This may lead to the classic clinical triad of hydrocephalus, chorioretinitis, and intracranial calcification. Congenital syphilis may, on occasion, produce hydrocephalus.

Bacterial meningitis can lead to an acute acquired hydrocephalus secondary to the effects of purulent exudate in the subarachnoid space or chronic acquired hydrocephalus secondary to inflammatory fibrosis. Bacterial meningitis is a more common cause of hydrocephalus than viral meningitis. Neonates with bacterial meningitis usually have simultaneous sepsis. Among the more common causes of neonatal meningitis are group B streptococci, *Escherichia coli, Listeria monocytogenes,* and *Klebsiella pneumoniae.* In general, bacterial infection tends to obstruct the cortical subarachnoid space, whereas granulomatous infection (e.g., tuberculosis) blocks the CSF cisterns, causing a hydrocephalus secondary to basal meningitis. The incidence of postinfectious meningitis in the United States has declined on the basis of improvements in neonatal diagnosis and treatment.

EXTERNAL HYDROCEPHALUS

External hydrocephalus is a benign condition characterized by macrocephaly and widening of the subarachnoid space, particularly over the frontal lobes and in the interhemispheric fissure[36] (Fig. 40-104). The sylvian fissures may be widened. Ventricular enlargement, if present, is usually mild. The condition has also been called benign external communicating hydrocephalus of infancy, and appears related to benign familial macrocephaly, sometimes called *familial macrencephaly,* discussed earlier.

External hydrocephalus is probably a mild variant of communicating hydrocephalus caused by defective resorption of CSF at the arachnoid villi. It is a generally benign condition associated with a large, square-shaped head that may cross percentiles. A family history of macrocephaly is frequently identified.[4] Cognitive and motor development are usually normal or minimally delayed. The head size gradually levels off and the condition usually remits by age 2 to 3 years. Surgical intervention is almost never required.[70]

The condition in neonates may not always be benign. Lorch and colleagues[51] examined the natural history of graduates of the neonatal intensive care unit with macrocephaly and "benign" extra-axial fluid collections and found that they were more likely to have developmental delay and cerebral palsy than macrocephalic survivors who did not stay in the neonatal intensive care unit. They were also more likely to have bronchopulmonary dysplasia and to require the use of extracorporeal membrane oxygenation than control subjects. When the clinical course of external hydrocephalus is not benign, other disorders should be considered. Infants with a significant motor delay or movement disorder, such as choreoathetosis, should undergo further evaluation to exclude a metabolic problem such as glutaric aciduria.

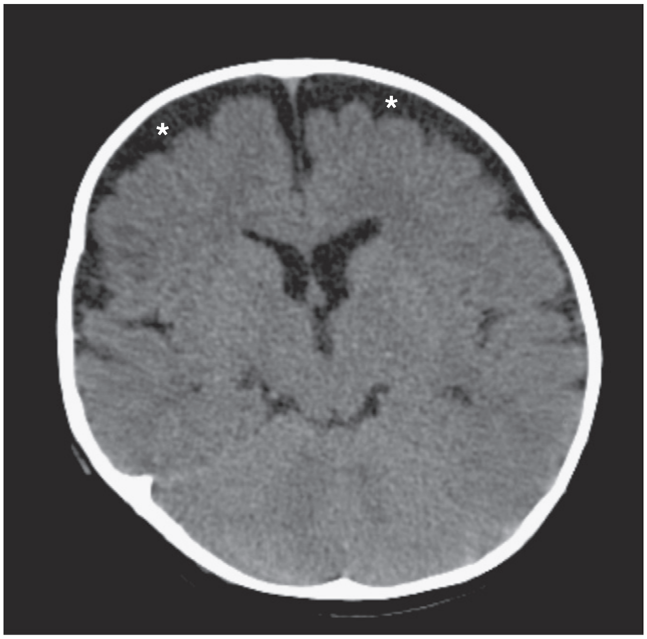

Figure 40–104. Benign external hydrocephalus of infancy. Computed tomography scan shows bifrontal extracerebral cerebrospinal fluid collections *(asterisks).*

HYDRANENCEPHALY

Hydranencephaly is a rare congenital anomaly marked by almost complete absence of the cerebral hemispheres. It is thought to occur as the result of a major in utero vascular insult during the second trimester, particularly bilateral occlusion of the carotid arteries. The brain undergoes intrauterine liquefaction and is essentially reduced to a bag of water, a meningeal sac containing CSF with a high protein content (Fig. 40-105). The diencephalon, brainstem, and posterior fossa structures are spared, and a thin occipital cortical rim may permit some visual function.

The newborn with hydranencephaly may appear neurologically normal at birth because of the normally functioning thalami and brainstem. Difficulty with visual fixing and following may be appreciated. The head size may be normal or even small at birth but can enlarge rapidly owing to malabsorption of the proteinaceous CSF. On occasion, the diagnosis of hydranencephaly is made after several months because of failure to achieve developmental milestones.

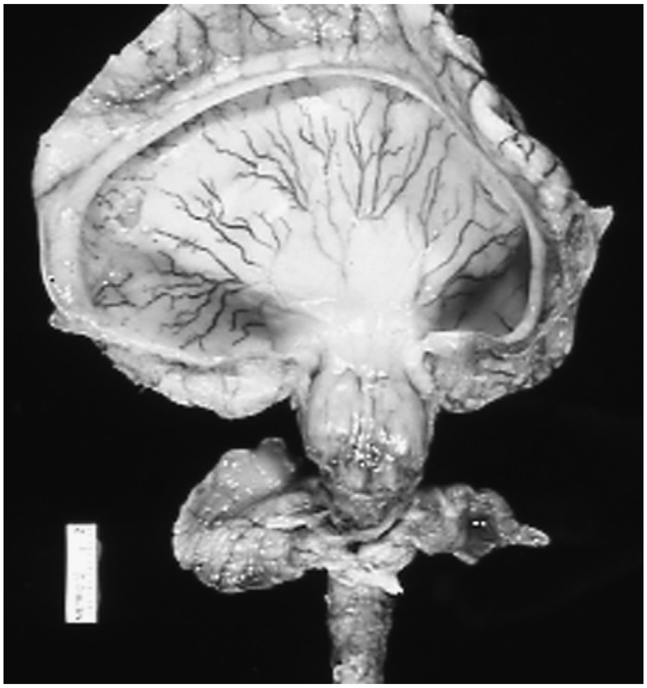

Figure 40–105. Hydranencephaly secondary to intrauterine liquefactive necrosis, sagittal specimen.

Significant macrocephaly may be treated with a ventriculoperitoneal shunt. The decision to shunt can be difficult because shunting is primarily done for social reasons and does not lead to an improved level of neurologic function. The long-term outcome for infants with hydranencephaly is poor, and most do not live for more than 1 or 2 years.

Hydranencephaly can be diagnosed by US, although CT and MRI are more accurate (Fig. 40-106). Hydranencephaly is distinguished from anencephaly by the presence of intact meninges and skull. It is important to distinguish between hydranencephaly and advanced hydrocephalus, which may have a similar clinical and radiographic presentation. The compressed cerebral mantle in hydrocephalus can expand, sometimes dramatically, after ventricular shunt placement.

INTRACRANIAL CYSTS

Intracranial cysts are rare causes of congenital macrocephaly. Arachnoid cysts arise from a duplication of the arachnoid membrane and are most commonly located in the middle cranial fossa, with up to 50% of intracranial arachnoid cysts located in this region (Fig. 40-107). They occur more frequently in boys than girls, and more often on the left side than the right. Arachnoid cysts may also be seen in the suprasellar area, over the cerebral convexity, and in the posterior fossa. Some cysts, such as suprasellar arachnoid cysts, may obstruct the ventricular system and cause hydrocephalus. Symptomatic arachnoid cysts are treated with fenestration or shunting procedures.

Neuroepithelial cysts are benign developmental cysts believed to have a neuroectodermal origin. Choroid plexus cysts are the most common of the neuroepithelial cysts. They are usually asymptomatic, can be diagnosed on prenatal US, and may involute spontaneously. Occasionally choroid plexus cysts can obstruct CSF flow in the ventricles and cause hydrocephalus. Intraventricular cysts may form in relation to the septum pellucidum, a midline ependyma-lined structure

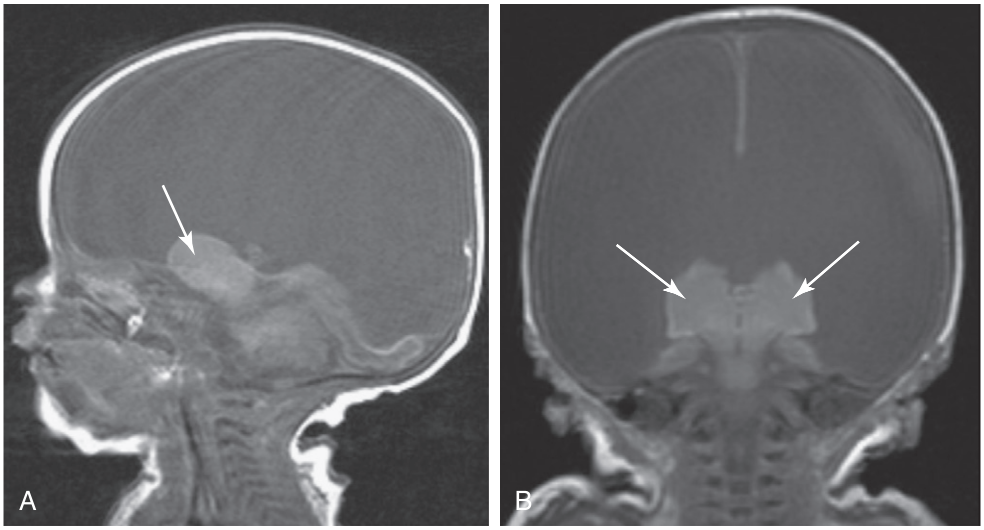

Figure 40–106. Hydranencephaly. T1-weighted sagittal (**A**) and coronal (**B**) magnetic resonance images show almost complete absence of the cerebral hemispheres, with preservation of the thalami *(arrows)* and hindbrain.

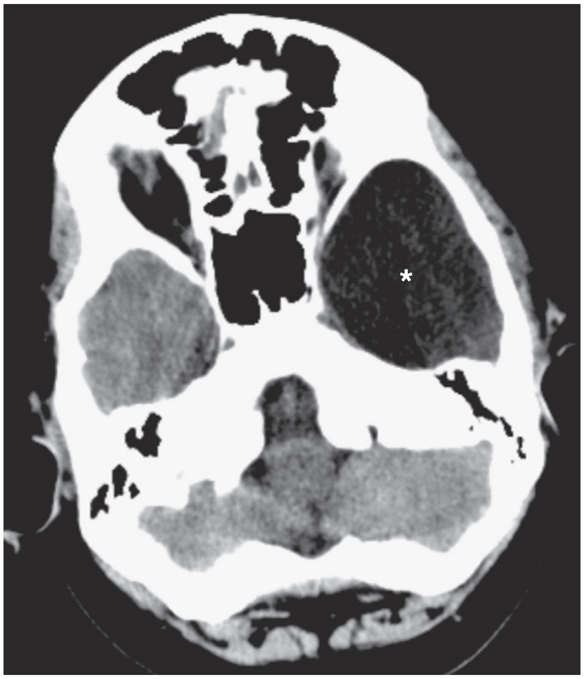

Figure 40–107. Arachnoid cyst. Computed tomography scan shows large arachnoid cyst *(asterisk)* of the left middle cranial fossa.

that separates the two lateral ventricles. In the embryo a cavity or cavum is present between the leaves of the septum pellucidum. This cavum of the septum pellucidum usually involutes shortly after birth but can persist asymptomatically in 20% of the population. Rarely, an intraventricular cavum septum pellucidum cyst develops that may obstruct the foramina of Monro and cause hydrocephalus. Even more rarely, a cyst of the cavum vergae, the posterior extent of the septum pellucidum, can enlarge and obstruct the foramina of Monro.

Presence or Enlargement of Other Structures

NEOPLASMS

Brain tumors in the neonate are uncommon. The most common presenting sign, regardless of histology, is macrocephaly, and most tumors are quite large.[80] Isaacs[38] reviewed 250 cases of fetal and neonatal brain tumors from the literature and found a survival rate of 28%. In children younger than 1 year of age, the preponderance of brain tumors is located supratentorially.[32] Slow-growing tumors such as the choroid plexus papilloma, low-grade astrocytoma, and ganglioglioma have the most favorable prognosis (Fig. 40-108). Rapidly growing tumors such as the primitive neuroectodermal tumor (Fig. 40-109) and malignant teratoma have a much poorer prognosis.

VASCULAR LESIONS

Rarely, macrocephaly in the newborn may be secondary to a *vein of Galen malformation*. Named for Claudius Galen of Pergamon, who described the deep venous system, this vascular

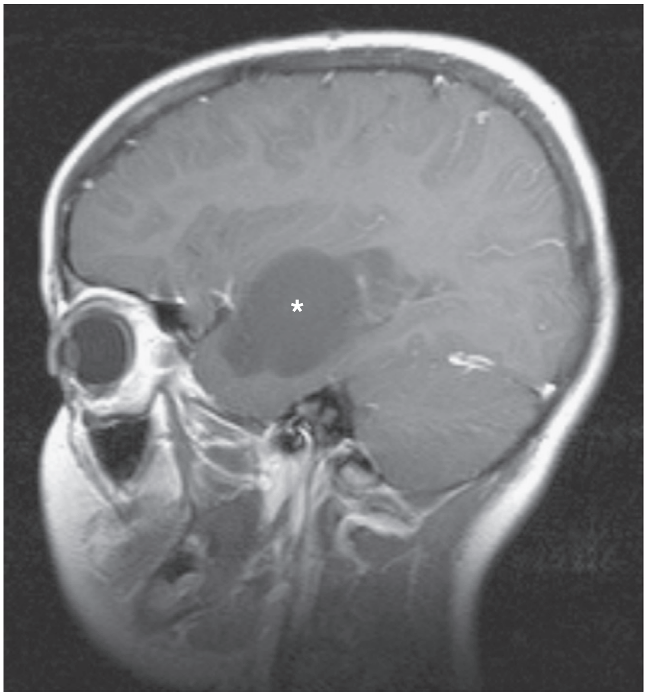

Figure 40–108. Dysembryoplastic neuroepithelial tumor, a low-grade primary neoplasm of the right temporal lobe *(asterisk)*. T1-weighted sagittal contrast-enhanced magnetic resonance image.

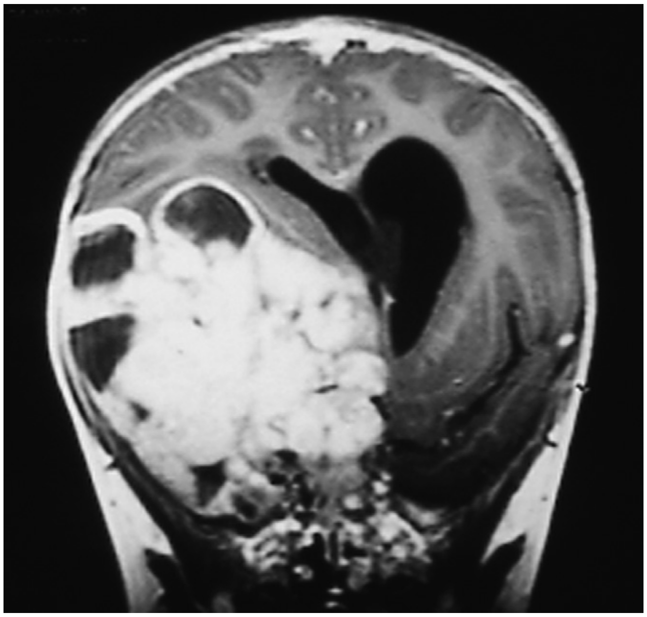

Figure 40–109. Large primitive neuroectodermal tumor of the right temporal lobe shown deforming the brain on a contrast-enhanced, T1-weighted coronal magnetic resonance image.

malformation arises in the first trimester of pregnancy as a persistent embryonic promesencephalic vein of Markowski.

The clinical presentation of a vein of Galen malformation in the neonate is dramatic. Massive shunting of blood through the arteriovenous fistula produces a refractory, high-output congestive heart failure. Cerebral venous hypertension and vascular steal lead to cerebral ischemia and infarction. A loud intracranial bruit can be auscultated at the vertex. Hydrocephalus may cause progressive head enlargement, occasionally requiring early shunting. Macrocephaly with seizures and developmental delay is a more common presentation in the infant than the newborn. Treatment is directed at endovascular obliteration of the fistula. The morbidity and mortality of the neonatal vein of Galen malformation remain high.

TRAUMA

See also Chapter 28.

Traumatic intracranial hemorrhage can lead to macrocephaly before the sutures are closed. The most common cause of traumatic macrocephaly in the neonate is subdural hematoma due to birth trauma. The hematoma is often located posteriorly, in relation to the tentorium (“tentorial tear”). The differential diagnosis includes postnatal trauma, including nonaccidental trauma, and bleeding diathesis (Fig. 40-110). The head circumference can increase rapidly, with a full anterior fontanelle. Consciousness may be impaired, with abnormal posturing and seizures. Diagnosis is best confirmed by CT. Subdural hematomas in the neonate may be unilateral or bilateral. Treatment may require craniotomy for acute bleeds. Subacute or chronic bleeds may be evacuated through a burr hole, sometimes with placement of a subdural drain or shunt.

INFECTION

Brain abscess is a rare cause of macrocephaly in the neonate. Risks factors include cyanotic congenital heart disease, pulmonary arteriovenous shunts, and impaired host defenses (e.g., congenital immunodeficiency states, human immunodeficiency virus infection). Brain abscess may develop from a contiguous otologic or paranasal sinus focus. The clinical presentation is one of systemic illness with elevated intracranial pressure and focal neurologic dysfunction related to location of the abscess. Causative organisms are most commonly aerobic and anaerobic streptococci. Other organisms include staphylococci, gram-negative bacilli, and anaerobes such as *Bacteroides*. Brain abscess is an infrequent complication of meningitis due to *Citrobacter diversus* or *Proteus mirabilis*. Diagnosis is made by CT or MRI, and treatment consists of antimicrobial therapy along with surgical drainage. Antiepileptic medication and corticosteroids are commonly used. It is essential to carry out a search for the underlying cause of the abscess.

Rarely, pyogenic infection occurs in the subdural space as the so-called subdural empyema. The presentation is similar to brain abscess and surgical drainage is an essential part of the treatment.

THE ABNORMALLY SHAPED HEAD

The two most common causes of a misshapen head in infancy are craniosynostosis and deformational plagiocephaly (Box 40-17). The former condition usually requires surgical correction and the latter condition is treated nonsurgically.

Craniosynostosis

Craniosynostosis (Greek *kranion*, “skull,” syn, “together,” *osteon*, “bone”) is a disorder marked by the premature fusion of one or more of the sutures of the skull. Premature cranial suture fusion leads to an abnormally shaped head and, sometimes, facial dysmorphism as well. Occasionally, particularly in cases of multiple suture fusion, craniosynostosis can lead to increased intracranial pressure and neurocognitive impairment (Fig. 40-111). Craniosynostosis is classified as *nonsyndromic* when there is isolated fusion of one or more sutures

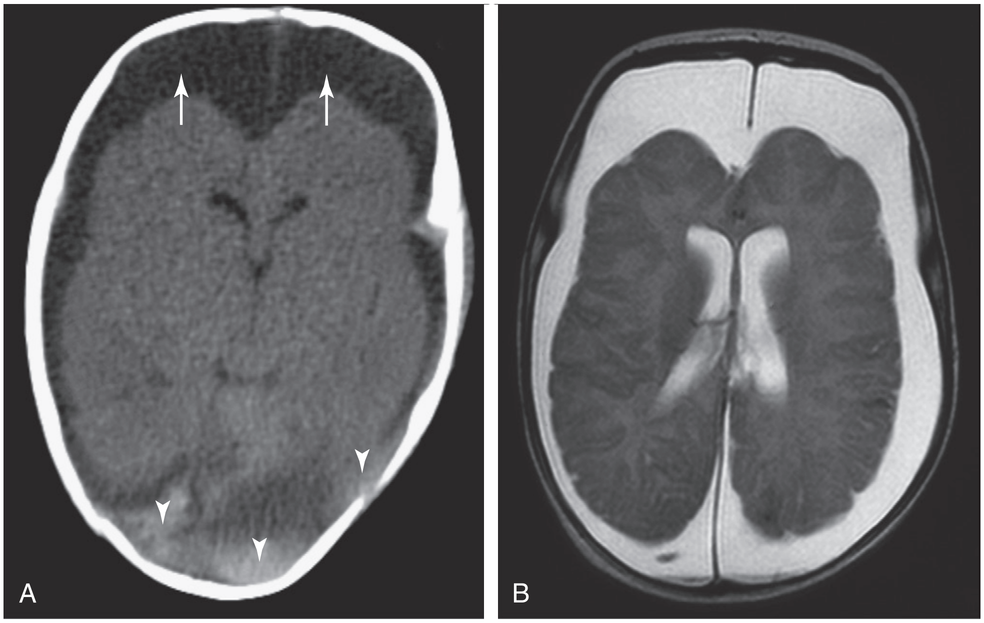

Figure 40–110. Nonaccidental trauma with bilateral subdural hematomas. **A**, Computed tomography scan shows bilateral frontal chronic subdural hematomas *(arrows)* and bilateral occipital acute subdural hematomas *(arrowheads)*. **B**, T2-weighted axial magnetic resonance image, same patient, shows the extensive bilateral subdural hematomas.

II. DEFORMATIONAL PLAGIOCEPHALY

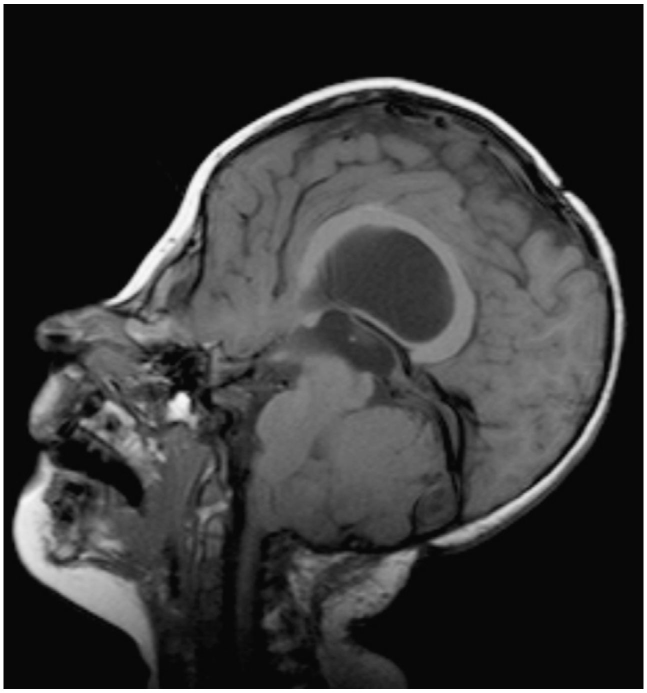

Figure 40–111. Brachyturricephaly secondary to multiple-suture synostosis, T1-weighted sagittal magnetic resonance image. Note the towering head. A basal frontal encephalocele is present with inferior herniation of the frontal lobes into the sphenoid sinus.

without associated anomalies and as *syndromic* when there is phenotypic expression of associated craniofacial, skeletal, and extraskeletal malformations. Craniosynostosis is also classified as *primary* or *secondary*. Most cases of craniosynostosis, whether nonsyndromic or syndromic, are due to primary closure of one or more cranial sutures. Occasionally, craniosynostosis may be secondary to systemic disorders, such as rickets, hyperthyroidism, polycythemia vera, and thalassemia.

In general, the bones of the skull vault grow perpendicular to the cranial sutures, and premature suture fusion restricts bone growth in the plane perpendicular to the fused suture (Virchow's law).[81] Other factors contribute to alterations in head shape, including compensatory bone growth at perimeter sutures, associated premature fusion of sutures at the cranial base in some cases, and mechanical factors such as increased intracranial pressure.

The etiopathogenesis of craniosynostosis is multifactorial. Intrauterine growth constraint, oligohydramnios, and abnormal lodging of the fetal head in the pelvis have been reported.[19,34] The timing of cranial suture fusion is a complex process. The dura signals the cranial sutures to remain patent until brain growth is complete. Alterations in the orchestration of these signals can lead to craniosynostosis. Advances in molecular genetics have implicated defects in fibroblast growth factor receptors (FGFRs) in many cases of craniosynostosis. Fibroblast growth factors are polypeptides whose binding to specialized receptors stimulates tyrosine kinase phosphorylation signaling pathways to direct cell growth and differentiation. Mutations in FGFRs have been found in syndromic and nonsyndromic forms of craniosynostosis. An FGFR2 mutation has been identified in Crouzon syndrome and in Apert syndrome (discussed later). FGFR1 and FGFR2 mutations have been identified in Pfeiffer syndrome. FGFR mutations have also been reported in nonsyndromic craniosynostosis. FGFR3 mutations have been isolated in some cases of nonsyndromic unisutural synostosis.[35,64]

The diagnosis of craniosynostosis is usually made on clinical criteria (Table 40-9). In cases of single suture involvement, skull radiographs confirm the diagnosis by showing sclerosis along all or part of the fused suture and compensatory changes. For complex cases, CT or three-dimensional CT scanning can help to delineate the pathologic process.

NONSYNDROMIC CRANIOSYNOSTOSIS

Sagittal Craniosynostosis

Premature fusion of the sagittal suture is the most common type of craniosynostosis. The prevalence has been estimated at approximately 1 per 1000 live births with a male-to-female

TABLE 40–9 Abnormal Head Shapes

Term	Definition	Fused Suture
Scaphocephaly	Boat head	Sagittal
Dolichocephaly	Long head	Sagittal
Clinocephaly	Saddle head	Sagittal
Brachycephaly	Short head	Bilateral coronal or lambdoid
Plagiocephaly	Oblique head	Unilateral coronal or lambdoid (or may be deformational)
Trigonocephaly	Triangular head	Metopic
Turricephaly	Towering head	Multiple
Acrocephaly	Peaked head	Multiple
Oxycephaly	Pointed head	Multiple
Hypsicephaly	High head	Multiple
Kleeblattschädel	Cloverleaf head	Multiple

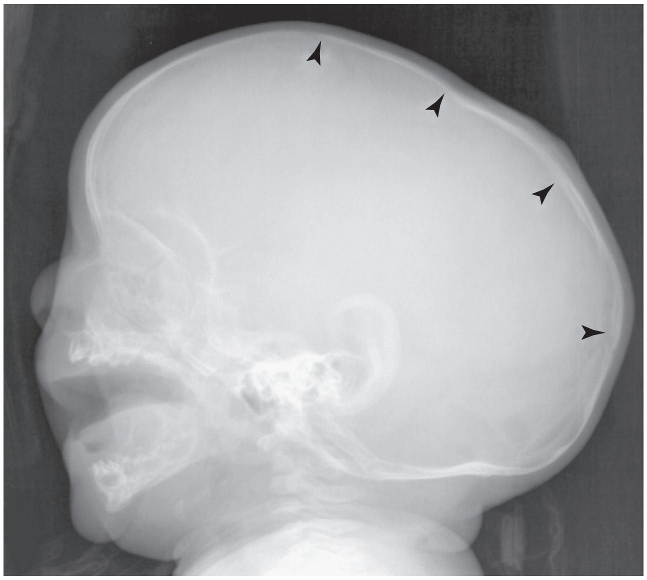

Figure 40–112. Sagittal synostosis. Skull radiograph shows fusion of the sagittal suture *(arrowheads)* with scaphocephaly and frontal bossing.

ratio of 4:1.[10] Sagittal synostosis is usually a sporadic disorder, but up to 10% of cases may be familial, with autosomal dominant inheritance.[47,59]

Infants with sagittal synostosis have a narrow, elongated head with a ridge along the sagittal suture (Fig. 40-112). The craniometric finding is described as scaphocephaly (Greek *skaphe*, “boat,” *kephale*, “head”) or dolichocephaly (Greek *dolichos*, “long”; see Table 40-9). The parietal diameter is narrow, often with compensatory changes that include frontal bossing, temporal hollowing, and an occipital protuberance (Fig. 40-113). Results of the neurologic examination are most often normal, although some investigators have reported coexistent findings including neurodevelopmental sequelae and even increased intracranial pressure (usually found only in association with multiple-suture synostosis).[41,66,79]

Numerous operative procedures are available for the correction of sagittal craniosynostosis. The surgical outcome is affected by age, with better results, in general, if the correction is performed early, before the age of 6 months.[10] Early correction allows the surgeon to take advantage of rapid brain growth in remodeling the skull—the brain weight triples in the first year of life. The major surgical risk associated with sagittal synostectomy, and for all forms of craniosynostosis surgery, is blood loss.

Unilateral Coronal Craniosynostosis

Premature fusion of one coronal suture produces a characteristic presentation of anterior plagiocephaly (Greek *plagio*, “oblique,” *kephale*, “head”) with flattening of the ipsilateral forehead and compensatory bossing of the contralateral forehead (Fig. 40-114). A ridge is palpable along the fused suture. The orbit on the affected side is shallow and the zygoma is foreshortened. The superolateral margin of the ipsilateral orbit is drawn upward and backward toward the elevated sphenoid wing, giving rise to the typical “harlequin” deformity on skull radiographs (Fig. 40-115). Facial asymmetry is frequent, often with ipsilateral deviation of the nasal root, contralateral deviation of the nasal tip, and vertical orbital

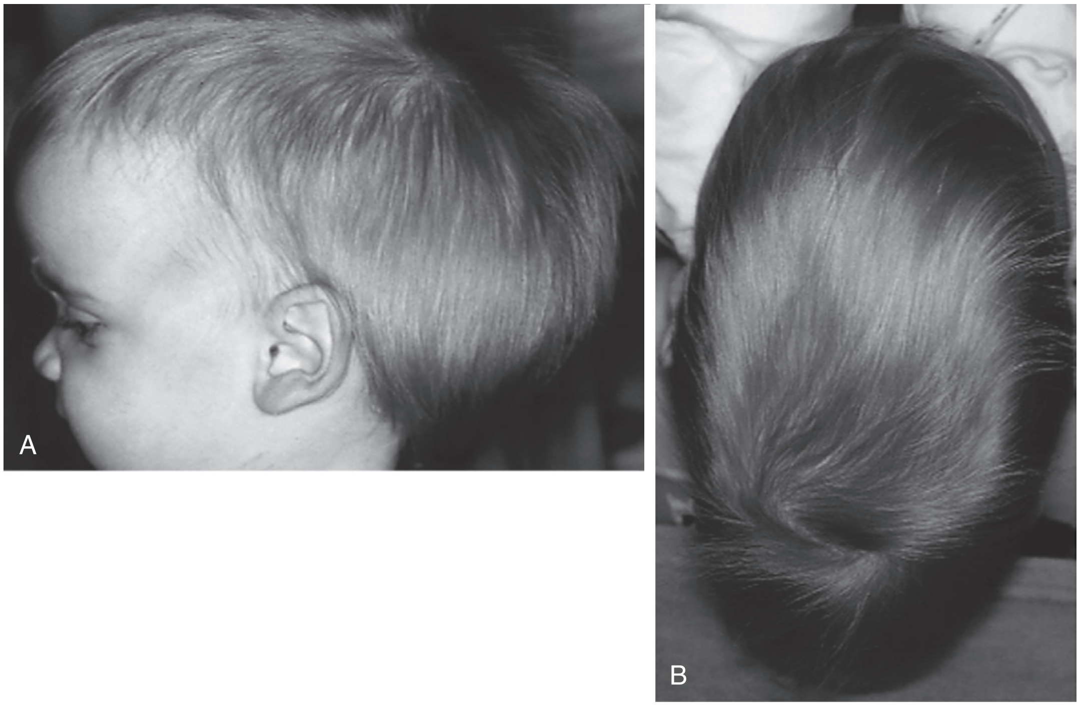

Figure 40–113. Sagittal synostosis, with scaphocephaly, frontal bossing, and protuberance at the occiput. **A**, Side view. **B**, Top view.

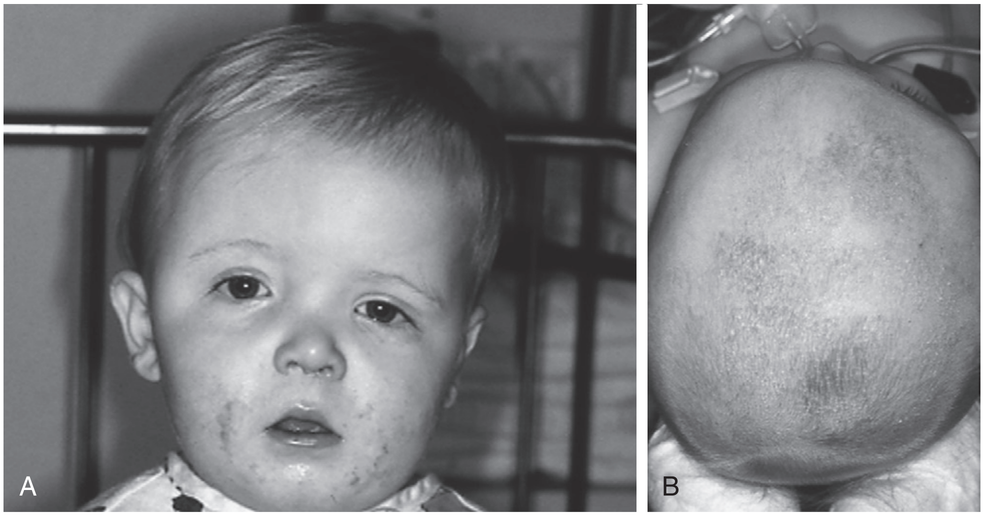

Figure 40–114. Unilateral right coronal synostosis. Note the facial asymmetry, ipsilateral frontal flattening, and vertical orbital dystopia with inferior displacement of the contralateral orbit. **A**, Front view. **B**, Top view.

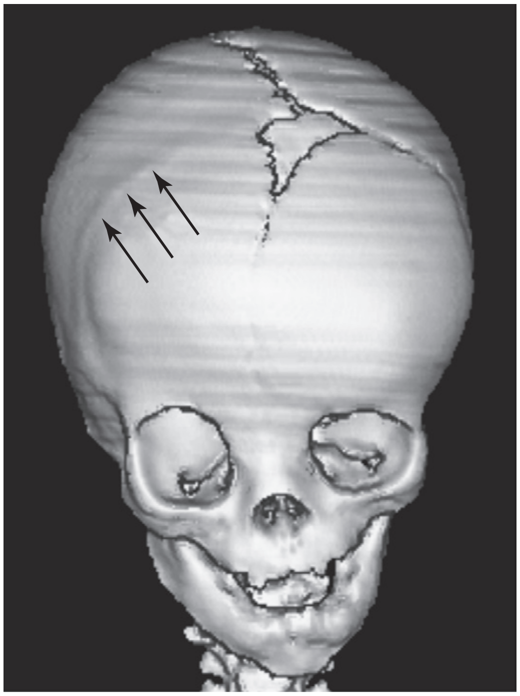

Figure 40–115. Unilateral right coronal synostosis *(arrows)* on three-dimensional computed tomography scan. The ipsilateral orbit is drawn upward and backward (harlequin eye).

dystopia with inferior displacement of the contralateral orbit. There is a slight female predominance.

Although considered a form of simple synostosis due to premature fusion of a single suture, unilateral coronal synostosis is often associated with fusion of other sutures at the cranial base, including the sphenozygomatic, sphenofrontal, and sphenoethmoidal sutures. These sutures constitute the "coronal ring" and interact with one another to affect growth of the anterior cranial fossa.

Surgical correction consists of craniotomy for anterior cranial vault reconstruction, which is usually carried out bilaterally because of the significant side-to-side asymmetry. The orbital bar is advanced as a "mortise and tenon" bone graft, with surgery facilitated by the introduction of absorbable plates and screws. Variable aesthetic results may be related to the heterogeneous presentation of unicoronal synostosis and the degree of involvement of sutures at the base of the coronal ring.[25]

Bilateral Coronal Craniosynostosis

Bilateral coronal craniosynostosis causes brachycephaly (Greek *brachy*, "short," *kephale*, "head") with palpable ridges over both coronal sutures. The head is foreshortened in the anteroposterior plane, often associated with compensatory widening and increased height (turricephaly; Fig. 40-116). As with unilateral coronal synostosis, there is a female predominance. Surgical repair is similar to that for unicoronal synostosis, with bifrontal craniotomy and orbital bar advancement.

Although bicoronal synostosis may be nonsyndromic, all children with brachycephaly due to premature fusion of the coronal sutures should undergo evaluation to rule out associated malformations. This is because premature fusion of both coronal sutures is the most common pattern observed in syndromic craniosynostosis.

Metopic Craniosynostosis

Premature fusion of the metopic suture accounts for approximately 10% to 20% of patients referred for evaluation of craniosynostosis.[21] As in sagittal synostosis, there is a male predominance. The clinical presentation is trigonocephaly (Greek *trigonon*, "triangle," *kephale*, "head"), which is a characteristic triangular head with a vertical keel over the forehead along the fused metopic suture (Fig. 40-117). The volume of the anterior cranial vault is small, often with associated hypotelorism, elevation of the lateral canthi, and temporal hollowing. A compensatory finding is widening of the biparietal diameter.

Metopic synostosis may occur as an isolated finding without associated neurologic abnormalities, or it may occur with intracranial anomalies including holoprosencephaly and agenesis of the corpus callosum. Infants with mild cranial deformities can be treated nonoperatively.

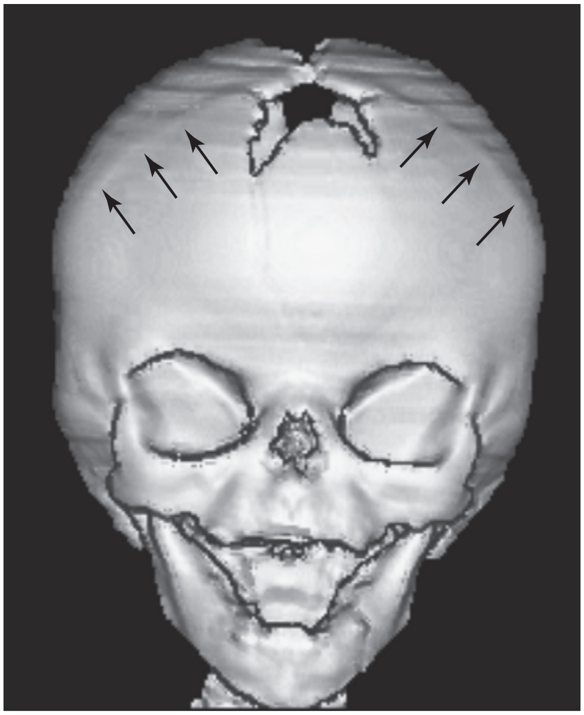

Figure 40–116. Bicoronal synostosis (*arrows*). Three-dimensional computed tomography scan shows brachyturricephaly.

Significant trigonocephaly usually requires surgical correction by bifrontal craniotomy and orbital bar advancement, which is usually carried out at approximately 6 months of age.

SYNDROMIC CRANIOSYNOSTOSIS

The craniofacial syndromes are relatively rare and often complex. Treatment has been aided by the formation of multidisciplinary craniofacial centers using a coordinated team approach. The craniofacial team includes specialists in anesthesiology, audiology, child life, critical care, developmental therapeutics, genetics, neurosurgery, nursing, occupational therapy, ophthalmology, oral surgery, orthodontics, otolaryngology, dentistry, pediatrics, plastic surgery, social work, and speech therapy.

Surgical correction of syndromic craniosynostosis is carried out by a craniofacial team that includes a pediatric neurosurgeon, plastic surgeon, and anesthesiologist. Surgery is directed at expanding the craniofacial skeleton and may include anterior cranial vault (fronto-orbital) expansion, posterior cranial vault expansion, and sometimes combined anterior and posterior cranial vault expansion.

The more common forms of syndromic craniosynostosis are discussed in the following paragraphs.

Crouzon Syndrome

Crouzon syndrome, or craniofacial dysostosis, was originally described by Octave Crouzon, a French neurologist, in 1912.[22] The incidence of Crouzon syndrome is approximately 1 in 25,000 births, with an autosomal dominant mode of inheritance. Approximately half of the cases of Crouzon syndrome are familial. The rest arise as spontaneous mutations, with the suggestion that advanced paternal age at conception is implicated in some instances.[46] A mutation of the FGFR2 gene has been identified in more than half the cases.

The clinical presentation of Crouzon syndrome is variable. Typical features include brachycephaly with exophthalmos and maxillary hypoplasia (Fig. 40-118). Subluxation of the globes can occur in advanced cases. The head shape is determined by the degree of premature cranial suture fusion. Craniosynostosis is usually not present at birth but evolves during the first year of life. The coronal sutures are fused in almost all cases. The lambdoid and sagittal sutures may also fuse prematurely, and there is often premature fusion of the basilar synchondrosis. Other facial features include strabismus, parrot-beak nose, small nasopharynx, arched palate, and mandibular prognathism. Extracranial features include fusion of cervical vertebrae, ankylosis of the elbows, and radial head subluxation. Hydrocephalus may occur, although mental retardation is infrequent. A crowded hypoplastic posterior fossa with herniation of the cerebellar tonsils below the foramen magnum

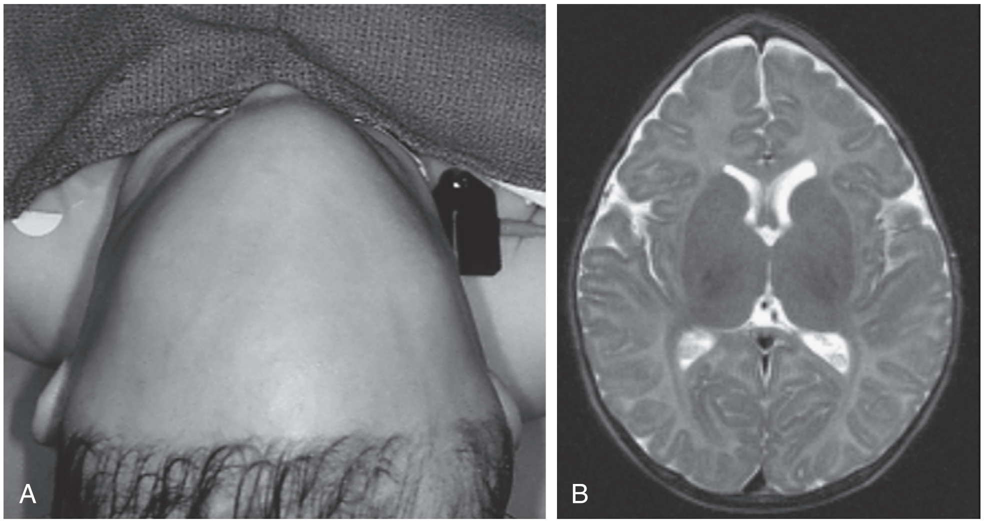

Figure 40–117. Trigonocephaly secondary to premature fusion of the metopic suture. **A**, Top view. **B**, T2-weighted axial magnetic resonance image.

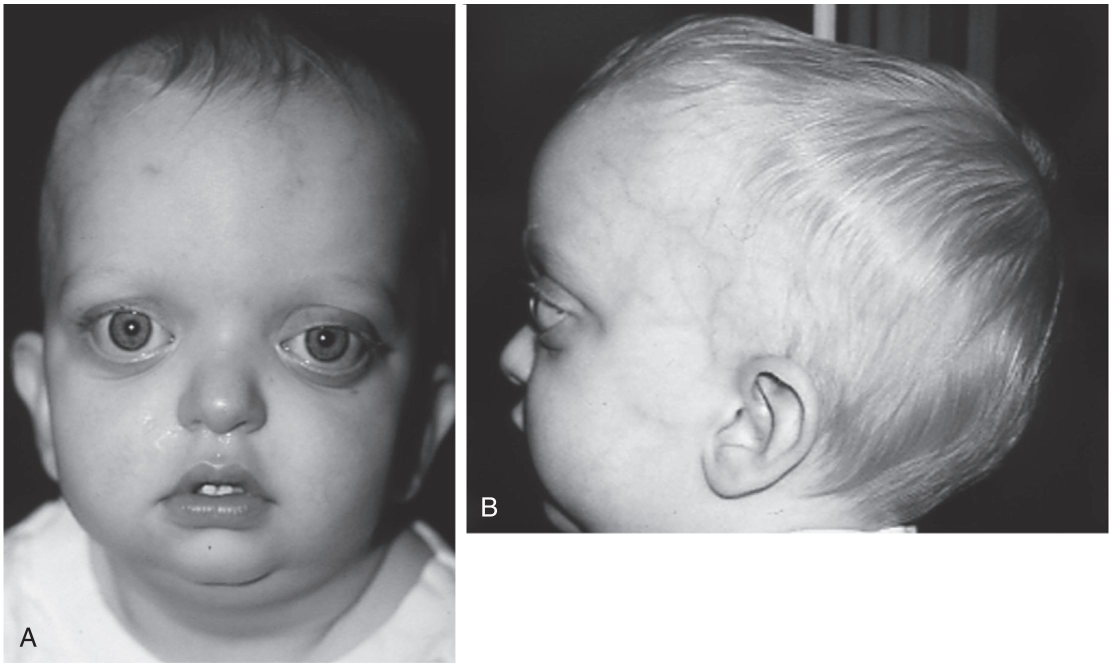

Figure 40–118. Crouzon syndrome (craniofacial dysostosis) with brachyturricephaly, exophthalmos, and maxillary hypoplasia. **A**, Front view. **B**, Side view.

(Chiari-like malformation) has been attributed to early fusion of the lambdoid sutures.[18]

Apert Syndrome

Apert syndrome, or acrocephalosyndactyly type 1, was originally described by the French pediatrician, Eugene Apert, in 1906, based on his observations of one personal case and several other cases published earlier.[5] The prevalence of Apert syndrome has been estimated to be 1 in 55,000 births.[67] Although autosomal dominant transmission has been described, most cases are sporadic, with advanced paternal age considered to be a risk factor.[68] Mutations tend to involve the *FGFR2* gene.[56]

Apert syndrome is characterized by the clinical triad of craniosynostosis, maxillary hypoplasia, and symmetric syndactyly of the hands and feet (Fig. 40-119). There is brachyturricephaly with a flattened occiput. Unlike Crouzon syndrome, the craniofacial anomalies are usually present at birth. Similar to Crouzon syndrome, the craniofacial appearance is determined by which sutures fuse prematurely. The coronal sutures are fused with a widely open anterior fontanelle and metopic suture. The lambdoid sutures are often prematurely fused, as are sutures at the cranial base. There is occasional premature fusion of the sagittal suture.

The cerebral ventricles are often enlarged, and widening of the subarachnoid spaces may be seen. The ventriculomegaly is often nonprogressive but may on occasion lead to frank hydrocephalus with increased intracranial pressure. Malformations of the corpus callosum and septum pellucidum have been described. Mental retardation is common. Mental retardation in Apert syndrome has been shown to correlate with anomalies of the septum pellucidum. Ventriculomegaly and corpus callosum anomalies, on the other

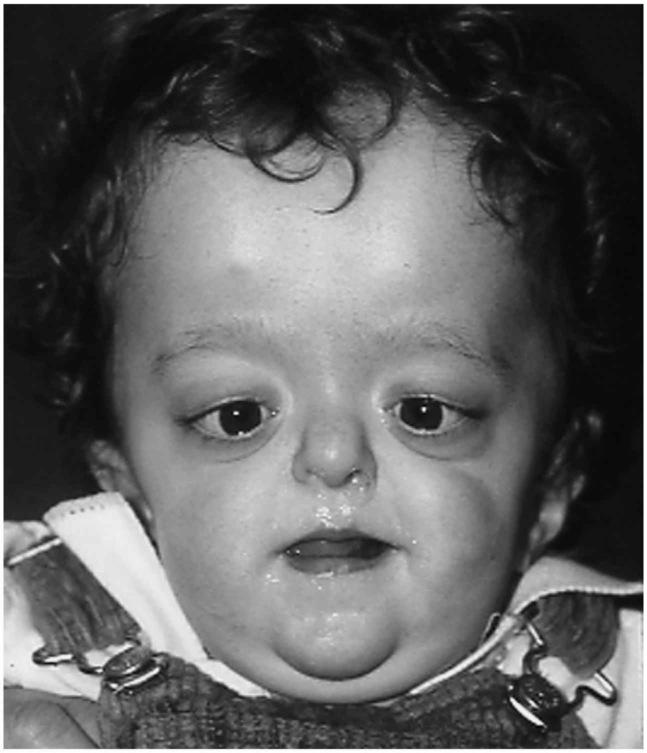

Figure 40–119. Apert syndrome (acrocephalosyndactyly type 1). There is brachyturricephaly, maxillary hypoplasia, hypertelorism with downsloping of the palpebral fissures, and a depressed nasal bridge. The child also has symmetric syndactyly of the hands and feet.

hand, appear to have no influence on intellectual achievement in patients with Apert syndrome.[67] As in Crouzon syndrome, cerebellar tonsillar herniation appears to be a function of a small posterior cranial fossa secondary to premature fusion of the lambdoid sutures.

Ocular hypertelorism (wide separation of the eyes) is present with proptosis and downward slanting of the palpebral fissures (antimongoloid slant).[17] Unlike in Crouzon syndrome, orbital subluxation is rare. Other craniofacial findings include maxillary hypoplasia with a high arched and occasionally cleft palate, relative prognathism with dental malocclusion, and low-set ears with eustachian tube abnormalities. The nose is short and beaked with a small nasopharynx and frequent associated respiratory complications.

The most distinguishing feature of Apert syndrome is symmetric polysyndactyly of the hands and feet, usually involving the second, third, and fourth digits. The syndactyly is both cutaneous and osseous. Other extracranial features may include finger duplication, short humerus, fusion of cervical vertebrae, and scoliosis.

Pfeiffer Syndrome

Pfeiffer syndrome, or acrocephalosyndactyly type 5, was described in 1964 by Rudolf Pfeiffer, a German geneticist who observed members of three generations of a family who had craniosynostosis, broad thumbs and great toes, and variable syndactyly of other digits.[62] Although Pfeiffer syndrome bears similarities to Crouzon and Apert syndromes, it appears to be a distinct disorder, with autosomal dominant inheritance or sporadic presentation. Mutations have been described on the *FGFR1* and *FGFR2* genes. Pfeiffer syndrome is rare, with an estimated incidence of 1 in 200,000 live births.[6]

The Pfeiffer phenotype shares features with Crouzon and Apert syndrome, including brachyturricephaly, exorbitism, maxillary hypoplasia, and mandibular prognathism. The coronal sutures are fused, with variable fusion of multiple sutures, including lambdoid, sagittal, metopic, and frontosphenoidal. Convolution markings on the inner surface of the skull can signify increased intracranial pressure (Fig. 40-120). Hydrocephalus may develop. The nose is beaked with a depressed nasal bridge, and the palate is high and arched with a bifid uvula. The thumbs and great toes are broad, short, and medially deviated. Syndactyly of the hands and feet is sometimes present.

Patients with Pfeiffer syndrome have been differentiated into three groups.[20] Type I Pfeiffer syndrome is the classic form that was described by Pfeiffer and is associated with normal intellect and a favorable prognosis. Types II and III are associated with severe central nervous system abnormalities, mental retardation, and developmental delay. Type III has the poorest prognosis and is differentiated from type II by the presence of a cloverleaf deformity of the skull.

Cloverleaf skull, or *kleeblattschädel*, describes a trilobar skull shape associated with multiple-suture synostosis. Kleeblattschädel is a descriptive term rather than a unique craniofacial syndrome. It represents the most severe form of multiple-suture craniosynostosis and has been reported in a variety of disorders, including Crouzon and Apert syndromes. It is seen most commonly in Pfeiffer syndrome type III. There is invariably hydrocephalus and increased intracranial pressure. The coronal, metopic, and lambdoid sutures are prematurely fused. The characteristic trefoil appearance is the result of brain herniating through the patent sagittal and squamosal sutures.

Saethre-Chotzen Syndrome

This craniofacial syndrome was described independently by Haakon Saethre, a Norwegian psychiatrist, in 1931, and F. Chotzen, a German psychiatrist, in 1932.[27,72] Saethre-Chotzen syndrome, or acrocephalosyndactyly type 3, is usually transmitted by autosomal dominant inheritance, with some cases occurring sporadically. Mutations of the *TWIST* gene, which maps to the short arm of chromosome 7 (7p21-22), have been identified.[12,29]

Clinical manifestations of Saethre-Chotzen syndrome include brachycephaly, maxillary hypoplasia, ptosis, hypertelorism, low-set hairline, small, round, angulated ears, and occasionally a beaked nose. There may be premature fusion of one or both coronal sutures, with metopic and lambdoid suture fusion found in some cases. Some individuals may have syndactyly of the second and third fingers, brachydactyly, and broad great toes. Intelligence is usually normal.

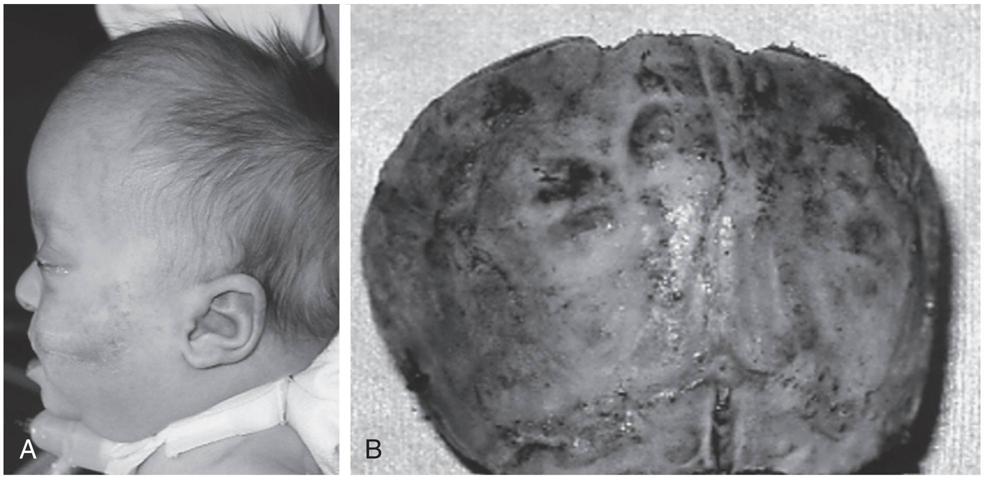

Figure 40–120. Pfeiffer syndrome (acrocephalosyndactyly type 5). **A**, Side view. There is brachyturricephaly, maxillary hypoplasia, and choanal atresia (note indwelling tracheostomy). The child also has broad thumbs and great toes. **B**, Undersurface of the skull at craniofacial reconstruction. Note the convolutional markings from increased intracranial pressure.

Deformational Plagiocephaly

DIAGNOSIS

Cranial asymmetry due to flattening of the occiput is a common condition that is seen with increased frequency in pediatric neurosurgical practices. In neurosurgical practice, cranial asymmetry due to occipital flattening may be the single most common cause for referral. The cranial asymmetry is usually due to mechanical factors and goes by a number of names, including *occipital plagiocephaly, deformational plagiocephaly, positional molding,* and *nonsynostotic occipital plagiocephaly.*

Posterior plagiocephaly is almost always deformational and rarely related to premature fusion of the lambdoid suture. Anterior plagiocephaly, on the other hand, is most commonly due to unilateral coronal synostosis (discussed previously). The incidence of true lambdoid synostosis is very low, estimated to occur in only approximately 3% of patients with craniosynostosis.[59,65]

The prevalence of deformational plagiocephaly has increased dramatically since 1992, when the American Academy of Pediatrics instituted the “back to sleep” program.[43,83] The prone position has been linked with the sudden infant death syndrome, and placing infants on their backs has led to a significant reduction in the frequency of this syndrome. The tradeoff has been an increase in the diagnosis of deformational plagiocephaly, with one institution reporting a sixfold annual increase in referrals to their center beginning in 1992, compared with the previous 13 years.[42]

The diagnosis of deformational plagiocephaly is usually made on the history and confirmed by the physical examination. Typically, the infant has a normal, rounded head at birth. After several weeks or months, the head assumes the shape of a parallelogram. Usually, the child has been lying on his or her back with the head favoring one direction. The parallelogram shape is best seen by examining the head from above. There is unilateral flattening of the occiput with an ipsilateral frontal prominence, creating a characteristic “windswept” appearance. The ipsilateral ear is displaced forward, but both ears are in the same horizontal plane (Fig. 40-121). Radiographic confirmation is unnecessary in typical cases. When skull films are obtained, they usually show patent lambdoid sutures, sometimes with associated perisutural sclerosis. Perisutural sclerosis has no diagnostic value because in true lambdoid synostosis the suture is obliterated radiographically.[59] A common CT finding in deformational plagiocephaly is prominent extra-axial CSF collections (widening of the subarachnoid spaces).[26]

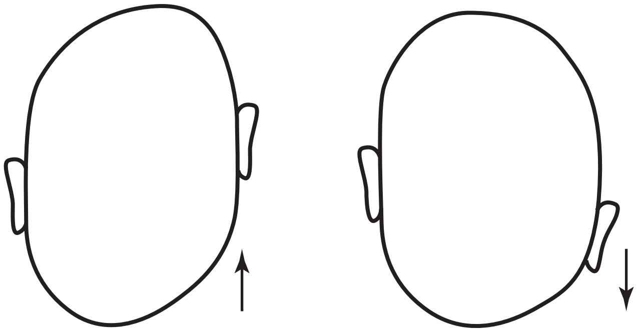

Figure 40–121. Deformational plagiocephaly (left) with right occipital flattening and anterior displacement of the ipsilateral ear. Right lambdoid synostosis (right) with right occipital flattening and posterior and inferior displacement of the ipsilateral ear.

Deformational plagiocephaly is differentiated from true lambdoid synostosis by several features. Statistically, true lambdoid synostosis occurs much more infrequently. Lambdoid synostosis is more likely to cause occipital flattening at the time of birth. Lambdoid synostosis, like deformational plagiocephaly, causes ipsilateral occipital flattening, but in lambdoid synostosis the ipsilateral ear is drawn posteriorly and inferiorly compared with the contralateral ear, and the skull shape is that of a rhomboid rather than a parallelogram. The degree of frontal asymmetry in lambdoid synostosis is less than in deformational plagiocephaly, and the frontal bossing tends to be contralateral rather than ipsilateral. The foramen magnum is drawn toward the fused suture in lambdoid synostosis and appears normal in deformational plagiocephaly. A ridge is sometimes, but not always, palpable along the fused suture in lambdoid synostosis.

Deformational plagiocephaly may be associated with multiple forces acting on the skull. Prenatal factors include uterine abnormalities such as a bicornuate uterus, uterine crowding due to a large fetus, twinning, or a pelvic lie. Postnatal factors include behavioral perseverance (child favors a particular position), torticollis with shortening or contracture of the sternocleidomastoid or trapezius muscles, head tilt from trochlear nerve palsy, and congenital vertebral disorders such as hemivertebrae or Klippel-Feil syndrome.[27]

TREATMENT

Management strategies for deformational plagiocephaly include preventive counseling, exercises and mechanical adjustments, skull-molding helmets, and surgery.

To prevent deformational plagiocephaly, parents should be instructed to alternate the head position when the newborn infant is put down to sleep in the supine position. Alternately placing the left occiput down and the right occiput down helps protect against cumulative deformational forces at a time when the skull is maximally deformable. The general principle is to avoid continuous pressure at one site. Prone positioning can be used when the infant is awake and under observation (“tummy time”). If plagiocephaly develops, the same principles of repositioning can be used. The position of the crib can be changed to reorient the infant to activity in the room.

Neck range-of-motion exercises are recommended, particularly if there is underlying torticollis. The stretching exercises are usually carried out for several months. They can be performed under supervision of the parents, sometimes with input from a physical therapist. It is recommended that the exercises be done frequently, in groups of three repetitions per exercise, at every diaper change. To stretch the sternocleidomastoid muscle, one hand is placed on the infant’s chest and the other rotates the head such that the chin touches the shoulder for approximately 10 seconds. The head is then rotated in the opposite direction. To stretch the trapezius muscle, the head is tilted such that the ear touches one shoulder for approximately 10 seconds. This is repeated for the other side.[61] Most cases of deformational plagiocephaly show some improvement with a regimen of repositioning and exercise. Once the infant begins to sit and spends less time in the recumbent position, further brain growth helps to reshape the head. The process by which the head becomes more rounded is usually slow and goes on for many months. Residual occipital flattening, if it is mild, is often masked by the growth of hair.

Skull-molding helmets can be used to reshape the head. These helmets, or headbands, are lightweight devices that are worn for most of the day, and are designed to place pressure on the prominent areas. Such external orthotic devices tend to work best in younger infants, whose skulls are thinner and more malleable. Headbands have been used to treat deformational plagiocephaly, with reports of improvement in anthropometrically measured cranial asymmetry.[68] Others, however, have reported similar improvement in cranial vault asymmetry using a regimen of aggressive repositioning and exercise only.[57] Exercise and repositioning can be used to treat most cases of mild to moderate deformational plagiocephaly, and headband can be used as therapy for more severe cases.

Surgery for posterior plagiocephaly is usually reserved for selected cases caused by premature fusion of one lambdoid suture (true lambdoid synostosis). Bilateral posterior cranial vault reconstruction gives results that are superior to simple unilateral strip craniectomy or unilateral craniotomy. Very infrequently there is a role for surgery in severe cases of deformational plagiocephaly refractory to nonsurgical measures.

PART 8

Myelomeningocele

Alan R. Cohen and Michele C. Walsh

DEFINING ANATOMY

A midline bony defect in the neural arches is present, usually involving several vertebrae in the lumbosacral region. Meninges, nerve roots of the cauda equina, and neural tissue, including dysplastic spinal cord, may protrude into a cystic structure over the lower back, which may or may not be covered by skin. Rarely, the neural structures herniate anteriorly into the retroperitoneal space. Myelomeningoceles are almost always associated with the Chiari II malformation.

EMBRYOLOGY AND PATHOGENESIS

Whether the primary pathogenesis is due to failure of closure of the bony elements, a disorder of neural induction, or reopening of a transiently closed posterior neuropore at 28 days' gestation, is an unresolved issue.[2] Risk of myelomeningocele in humans and experimental animals is increased with folic acid deficiency and exposure of the embryo to excessive retinoic acid or vitamin A. Many neural tube defects can be prevented by preconceptional folic acid supplementation of 0.4 mg per day.[4] Although the condition is not a direct mendelian trait, mothers with one affected infant are at higher risk for another than the control population and should receive 4 mg per day of folic acid. This malformation involves all ethnic groups but is higher in some populations such as the Irish.

Specific Types

See also Chapter 11.

A *meningocele* is a cystic dilation of the meninges associated with spina bifida and a defect in the overlying skin. The spinal cord and nerve roots are normal in their structure and position in the spinal canal. Accordingly, infants with meningoceles typically do not show neurologic deficits.

A *myelomeningocele* is a lesion identical to the meningocele but with associated abnormalities in the structure and position of the spinal cord. A myelomeningocele results from failure of primary neurulation. The neural tube does not fuse dorsally, leaving an open neural placode, similar to an open book. The majority of myelomeningoceles are located in the low thoracolumbar spine or more distally. Affected infants typically show neurologic deficits below the level of the lesion. Emerging evidence suggests that in addition to failure of neural tube closure, a primary disruption of brain development may be involved.[1,3]

Spina bifida occulta refers to a nonfusion of one or more of the posterior arches of the spine, usually in the lumbosacral region. A frequent abnormality found at L5 in 30% of adults, the lesion is of neurologic consequence only when associated with underlying abnormalities such as tethering of the spinal cord. This condition comprises a low-lying conus below L1/L2, best diagnosed by MRI. It may require prophylactic surgery as growth provides traction. Significant associated abnormalities usually are signaled by the presence of a neurocutaneous signature such as a hemangioma, a patch of abnormal hair, a dimple, or a lipoma in the lumbosacral area. Underlying lesions can include diastematomyelia (split cord malformation), spinal lipomas, dermoids, and dermal sinuses.

CLINICAL EXPRESSION

The extent of neural tissue involvement in the myelomeningocele determines the severity of the deficit in motor and sensory function involving the lower extremities and the presence of involvement of bladder and bowel functions (Table 40-10). Many infants with lesions at the L5 to S1 level ultimately will ambulate, with or without short leg braces. Although the ability to predict later function from the level of early neurologic function has been shown to be only modestly accurate, long-term outcomes of patients with myelomeningocele are favorable. In a longitudinal 25-year study of 220 consecutive patients with myelomeningocele, 78% had hydrocephalus treated with ventricular peritoneal shunts.[7] Sixty-three percent required one or more shunt revisions. A tethered cored ultimately developed in 40 (20%) patients. Over a 25-year follow-up period, there were 5 (2%) deaths, and 18 patients (9%) with severe neurologic morbidity. Ninety-seven percent of survivors with an initial lesion below L2 were functioning independently, attending regular schools, and achieved "social continence." In a separate report studying 50 teenagers with myelomeningocele, 21 patients were dependent on wheelchairs. Overall, this group described diminished health-related quality of life, specifically regarding emotional well-being, self-esteem, and peer relations.[5]

Infants with lesions at L3 to L4 might be ambulatory with the assistance of long leg braces and crutches. These infants are prone to paralytic hip dislocation. Infants with lesions at L1 to L2 or higher are completely paraplegic with no functional ambulatory ability (Table 40-11).

Hydrocephalus is a frequent associated complication of myelodysplasia. In general, the more rostral the presence of the myelomeningocele, the more likely hydrocephalus will exist, as a consequence of either the Chiari II malformation or aqueductal stenosis.

TREATMENT

A newborn with a myelomeningocele presents the clinician with difficult decisions about what to tell parents and whether to close the spinal defect surgically. Surgery should be undertaken within the first 72 hours after birth to prevent further deterioration of the spinal cord and nerve roots, and to prevent infection (meningitis). Fetal therapy of myelomeningocele is discussed in Chapter 11.

Factors that influence surgical planning include size and location of the lesion, the technical feasibility of surgical closure, the prognosis for ambulation, the presence or absence of associated abnormalities (hydrocephalus, kyphosis, or other major structural abnormalities), the availability of

TABLE 40–10 Motor Examination of Lower Extremities in Children with Meningomyeloceles

	SPINAL SEGMENT		
Movement	**Lumbar**	**Sacral**	**Muscle**
Hip			
Flexion	1, 2, 3, 4		Iliopsoas, rectus femoris
Adduction	2, 3, 4		Adductors
Abduction	4, 5	1	Gluteus medius
Extension	4, 5	1, 2	Gluteus maximus, obturator
Knee			
Extension	2, 3, 4		Quadriceps
Flexion	5	1, 2	Hamstrings
Foot			
Dorsiflexion	4, 5	1	Tibialis anterior
Plantar flexion	5	1, 2	Soleus, gastrocnemius

TABLE 40–11 Deficit and Prognosis of Meningomyeloceles Related to Site of Lesion

Motor/Sensory Level	*Maximum Motor Deficit*	*Prognosis for Ambulation*	*Risk of Hydrocephalus*
L5-S1	Dorsiflexion and plantar flexion of feet, weakness of glutei	Will ambulate with or without short leg braces; outlook good	60%
L3-L4	Involvement of quadriceps and hamstrings, plus above	May be able to ambulate with long leg braces and crutches; paralytic hip dislocation	86%
L1 and L2 or above	Complete paraplegia	No functional ambulation	96%

personnel and a facility to provide adequate care for the infant, the infant's family structure, and the attitudes of the family toward the defect and its consequences. The usual decision is to proceed with early surgical closure of the spinal defect, followed by placement of a ventriculoperitoneal shunt if hydrocephalus is present (see Part 7 of this chapter). Thereafter, the infant requires long-term neurosurgical, orthopedic, and urologic follow-up to maintain shunt stability, promote ambulation if possible, and minimize the untoward effect of multiple urinary tract infections. In the past, infants with an associated severe chromosomal malformation (e.g., trisomy 18) were not repaired. Currently, most infants are offered palliative surgical care to correct the defect. This facilitates discharge and eases the family's burden of caring for these infants at home.

CHAPTER 41

Follow-up for High-Risk Neonates

Deanne Wilson-Costello and Maureen Hack

Advances in obstetric and neonatal care have been responsible for the improved survival of high-risk neonates. A major concern persists, however, that newer therapies may result in an increased number of permanently disabled infants. The earliest follow-up studies of preterm infants after the introduction of modern methods of neonatal intensive care in the 1960s described a decrease in adverse neurodevelopmental sequelae compared with that of the preceding era.[76] During the 1980s and 1990s, there was a continued decrease in mortality, and thus the absolute number of both healthy and neurologically impaired survivors increased.[22,72,73] Furthermore, the survival of increasing numbers of extremely immature infants with low birthweight resulted in a relatively high disability rate in the subpopulation of infants born weighing less than 750 g or born at less than 26 weeks' gestation.[33,37,105] Since 2000, mortality rates for infants with very low birthweight have leveled off. Several studies suggest declining rates of neurodevelopmental impairment, including cerebral palsy.[74,78,101]

Conditions of presumed genetic and prenatal origin account for more children with neurodevelopmental dysfunction than disorders arising out of the perinatal period. Infants who are at highest risk for later neurodevelopmental problems resulting from perinatal sequelae include those who had severe asphyxia, severe intracranial hemorrhage, infarction or periventricular leukomalacia, meningitis, seizures, respiratory failure resulting from pneumonia, persistent fetal circulation or severe respiratory distress syndrome, and multisystem congenital malformations, as well as children born with extremely low birthweight or at extremely early gestational age (Boxes 41-1 and 41-2). The rates of health problems and neurodevelopmental sequelae increase with decreasing birthweight and gestation (Tables 41-1 and 41-2).

Follow-up programs should be an integral extension of every neonatal intensive care unit. Specialized care must be made available for problems of growth, development, and chronic disease and is best provided within the setting of a neonatal follow-up program. The follow-up care should, if possible, initially be provided by the neonatologist together with the family pediatrician. If there are developmental or neurologic problems, the child should also be referred to a subspecialist or a child development center.

The initial continuity of care is important to reassure the family that the same personnel responsible for the life-saving decisions are continuing to assume responsibility for the child's adaptation into home life. Furthermore, even if the neonatal staff members do not continue the follow-up after infancy or early childhood, they will benefit greatly by maintaining contact with the infants leaving the nursery and recognizing the sequelae of prematurity. Growth (weight, height, and head circumference), neurologic development, psychomotor and cognitive development, vision, and hearing all should be sequentially assessed.

In planning neonatal follow-up programs, various options are possible.[8] These depend on the available resources. A minimal requirement for the clinical monitoring of outcomes is a periodic assessment of growth and neurosensory development during the first 2 years of life. The ideal is a comprehensive program involving all aspects of care, including well-baby care, evaluation of outcome, social and educational intervention, and therapy when needed. A home nurse visiting program, especially during the early postdischarge period, and parent support groups for selected high-risk conditions (e.g., children with chronic lung disease) also should be considered. There is evidence that educational enrichment during infancy and early childhood might improve the outcome of high-risk and preterm infants, especially those from socioeconomically deprived groups.[51]

Outcomes from different units might not be comparable because they are heavily influenced by the demographic and socioeconomic profile of the parents, the incidence of extreme prematurity, a selective treatment or admission policy, the percentage of inborn patients at any center, and the rate of follow-up.[96] Intercenter differences in neonatal sequelae and outcome are well described.[34,99] Regional results therefore reflect a more accurate picture of outcome because

BOX 41–1 Factors Affecting Outcome of the Infant with Very Low Birthweight

- Birthweight <750 g or <25 weeks' gestation
- Periventricular hemorrhage (grades III and IV) or infarction
- Periventricular leukomalacia
- Persistent ventricular dilation
- Neonatal seizures
- Chronic lung disease
- Neonatal meningitis
- Subnormal head circumference at discharge
- Parental drug abuse
- Poverty and parental deprivation
- Coexisting congenital malformation

BOX 41–2 Factors Affecting Outcome of the Term Infant

- Birth depression or asphyxia
- Persistent fetal circulation
- Meningitis
- Intrauterine growth failure
- Intrauterine infections
- Symmetric growth restriction (microcephaly)
- Major congenital malformations
- Neonatal seizures
- Extracorporeal membrane oxygenation (ECMO) and nitric oxide therapy
- Persistent hypoglycemia
- Severe hyperbilirubinemia

they include all infants born in an area. This is the ideal situation, but such studies are rarely available in the United States. Individual centers should be aware of their own patients' social risk factors and rates of neonatal morbidity and, if possible, maintain their own follow-up outcome data.

Data from Hack M, et al: Long-term developmental outcomes of low birth weight infants, *Future Child* 5:176, 1995.

Any evaluation of the outcome studies of high-risk infants must include the population status (inborn, outborn, or regional) and the choice of a comparison group that includes either a normal birthweight group or infants within a similar birthweight or gestational age range who do not have the condition or therapy under study. It also is essential to control for sociodemographic factors such as maternal marital status, ethnicity, and education and to consider possible genetic factors when evaluating cognitive outcome or school performance.

Consideration of neonatal mortality is important for judging the aggressiveness and level of neonatal care, which might influence the quality of outcome of the survivors.[59] Other factors to be considered are the rate of loss of infants to follow-up, the neonatal and postdischarge death rate, the age at follow-up, and the method of follow-up.[102] Two years is the earliest age to get a fairly reliable assessment of neurodevelopmental outcome. At age 4 to 5 years, cognitive function and language can be better measured, and follow-up to age 7 to 9 years allows an assessment of subtle neurologic and behavioral dysfunction and school academic performance (Fig. 41-1).[35,43,94]

Because it is impossible to provide ongoing high-risk follow-up care for all infants treated in the neonatal intensive care unit, specific criteria have been proposed to identify children at greatest risk for sequelae.[11] Traditionally, follow-up programs primarily targeted children with birthweight of less than 1500 g or gestational age of less than 32 weeks. However, more recent therapies, such as inhaled nitric oxide and extracorporeal membrane oxygenation, have increased the demand for highly specialized follow-up clinics for term infants with persistent pulmonary hypertension, meconium aspiration, and sepsis.

In addition, a growing number of infants with major congenital malformations such as congenital diaphragmatic hernia now survive the neonatal period to require intensive ongoing follow-up support. University-affiliated follow-up programs could select additional candidates for follow-up in the high-risk clinic on the basis of participation in specific research studies. Because of the significant costs associated with evaluating all eligible follow-up patients in the clinic setting, parent and teacher questionnaires have been suggested. These

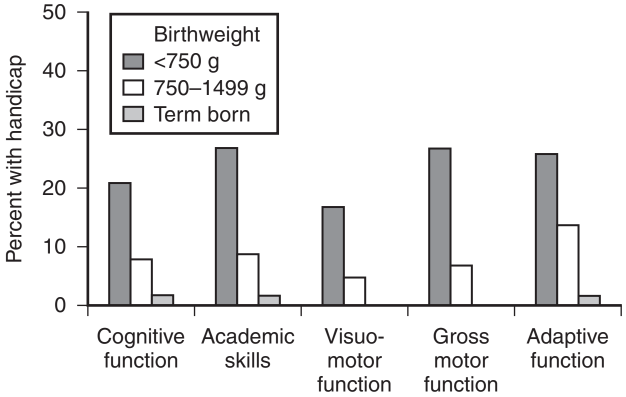

Figure 41–1. Percentage of 6- to 7-year-old children born from 1982 to 1986 by birthweight (<750 g, 750-1499 g, and term born) with subnormal functioning. Subnormal functioning was defined as a standard score of <70 for cognitive function, academic skills, visuomotor function, and adaptive function and a score of <30 for gross motor function. *(Data from Hack M, et al: School-age outcomes in children with birth weights under 750 grams,* N Engl J Med *331:753, 1994.)*

questionnaires typically provide a checklist of various individual measures of health status and disability (Box 41-3).[52]

BOX 41–3 Suggested Criteria for Severe Disability at Age 2 Years

MALFORMATION
Impairs the performance of daily activities

NEUROMOTOR FUNCTION
Unable to sit
Unable to use hands to feed
Unable to control head movement (or no head control)

SEIZURES
More than 1 per month despite treatment

AUDITORY FUNCTION
Hearing impaired despite aids

COMMUNICATION
Unable to comprehend
Unable to produce more than five recognizable sounds

VISUAL FUNCTION
Blind or sees light only

COGNITIVE FUNCTION
About 12 months behind at 2 years

OTHER PHYSICAL DISABILITY

Respiratory
- Requires continual oxygen therapy
- Requires mechanical ventilation

Gastrointestinal Function
- Requires tube feeding
- Requires parenteral nutrition

Renal Function
- Requires dialysis

Growth
- Height or weight more than 3 standard deviations below mean for age

From Johnson A: Follow up studies: a case for a standard minimum data set, *Arch Dis Child* 76:F61, 1997.

MEDICAL PROBLEMS

Neonatal medical complications include chronic lung disease, intraventricular hemorrhage, retinopathy of prematurity, hearing loss, increased susceptibility to infections, and sequelae of necrotizing enterocolitis. These in turn can contribute to multiple rehospitalizations after discharge, poor physical growth, and an increase in postneonatal deaths. Children with neurologic sequelae such as cerebral palsy and hydrocephalus have a higher rate of rehospitalization for conditions such as shunt complications, orthopedic correction of spasticity, and eye surgery. Furthermore, a high percentage of children with chronic lung disease, extreme prematurity, or both, require rehospitalization during their first year.

Although the incidence of severe bronchopulmonary dysplasia has decreased in recent years, some children require home oxygen and other medications such as diuretics or bronchodilators after discharge. They are prone to recurrent respiratory infections, poor nutrition, and growth failure related to their chronic lung disease and thus require multispecialty follow-up, including neonatal, developmental, nutrition, and pulmonary specialists. The medical complications of prematurity tend to diminish after the second year of life, although airway reactivity and asthma may persist.

Physical Growth

Intrauterine or neonatal growth restriction, or both, occur commonly in preterm infants. The poor neonatal growth is related to inadequate nutrition during the acute phase of neonatal disease, feeding intolerance, and chronic medical sequelae that result in increased calorie requirements. These include chronic lung disease, recurrent infections, and malabsorption secondary to necrotizing enterocolitis. The use of postnatal steroids may also contribute to growth failure. Catch-up growth may occur later in infancy and childhood. Poor feeding in chronically ill or neurologically impaired children may also affect neonatal growth. The parents' size contributes to the eventual growth outcome.

Intrauterine and neonatal brain growth failure and lack of later brain catch-up growth can affect cognitive functioning.[31] Many infants with very low birthweight who are small for gestational age also have subnormal head growth, and brain growth failure can occur during the neonatal period. Catch-up brain growth can occur during infancy in infants with very low birthweight who are either appropriate or small for gestational age; however, as many as 10% of infants with very low birthweight who are appropriate for gestational age and 25% who are small for gestational age still have a subnormal head size at 2 to 3 years of age that persists at school age. Poor growth attainment is especially apparent in the child with an extremely low birthweight or gestational age (Fig. 41-2).

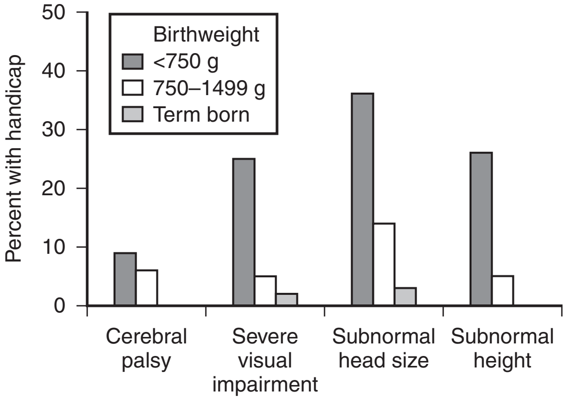

Figure 41–2. Percentage of 6- to 7-year-old children born from 1982 to 1986 by birthweight group (<750 g, 750-1499 g, and term born), with each of four major impairments. Cerebral palsy was defined to include hemiplegia, diplegia, or quadriplegia. Visual impairment includes unilateral or bilateral blindness or visual acuity of <20/200 without glasses in at least one eye. Subnormal head size and height are <2 standard deviations below the mean for the child's age. *(Data from Hack M, et al: School-age outcomes in children with birth weights under 750 grams,* N Engl J Med *331:753, 1994.)*

Growth after discharge is a good measure of physical, neurologic, and environmental well-being. To promote optimal catch-up growth of high-risk infants, neonatal nutrition must be maximized. This is especially important because catch-up of head circumference occurs only during the first 6 to 12 months after the expected date of delivery.[31] During recent years, increased-calorie postdischarge formulas have been introduced. These formulas have been associated with improved growth to 9 months. Reports of osteopenia or rickets of prematurity have increased with the improved survival of extremely premature infants whose birth precedes the period of greatest in utero mineral accretion. Although rickets of prematurity appears to be a self-resolving disease, postdischarge formulas with higher calcium and phosphorus content have enhanced growth and bone mineral accretion among preterm infants.[75]

NEURODEVELOPMENTAL OUTCOME

Transient Neurologic Problems

A high incidence of transient neurologic abnormalities, ranging from 40% to 80%, occurs in high-risk infants. These include abnormalities of muscle tone such as hypotonia or hypertonia (occurring as poor head control at 40 weeks' postconceptional age), poor back support at 4 to 8 months, or a slight increase in muscle tone of the upper extremities. Because some degree of physiologic hypertonia normally exists during the first 3 months, it may be difficult to diagnose the early developing spasticity related to cerebral palsy.[27]

Children who will later develop cerebral palsy often initially have hypotonia (poor head control and back support) and only later develop spasticity of the extremities. Spasticity during the first 3 to 4 months is, however, a poor prognostic sign. Persistence of primitive reflexes also might be a sign of early cerebral palsy. Although mild hypotonia or hypertonia persisting at 8 months usually resolves by the second year, it might indicate later subtle neurologic dysfunction.[20]

Major Neurologic Sequelae

Major neurologic sequelae can usually be diagnosed during the latter part of the first year of life or even earlier if they are very severe. Major neurologic disability is usually classified as cerebral palsy (spastic diplegia, spastic quadriplegia, or spastic hemiplegia or paresis), hydrocephalus (with or without accompanying cerebral palsy or sensory deficits), blindness (usually caused by retinopathy of prematurity), seizures, or deafness (Box 41-4). The intellectual outcome can differ greatly according to neurologic diagnosis. For example, children with spastic quadriplegia usually have severe developmental delay, whereas children with spastic diplegia or hemiplegia may have better mental functioning. Cognitive function is not well measurable until after 2 to 3 years of age, especially among neurologically impaired children.

Most neurologic problems either resolve or become permanent during the second year of life. During the second year, the environmental effects of maternal education and social class begin to play a major role in the various cognitive outcome measures. Further problems could emerge during the school-age years. These include subtle motor, visual, and behavioral difficulties even among children with normal intelligence.[92] These are best diagnosed and treated in a psychological and educational, rather than a medical, follow-up setting.

Cerebral palsy, an umbrella term that refers to "a group of non-progressive, but often changing, motor impairment syndromes secondary to lesions of the developing brain" occurs about 70 times more frequently among infants with extremely low birthweight than among controls with normal birthweight.[66] Risk factors include periventricular echolucencies noted on cranial ultrasound, intrauterine and neonatal infection, hypotension, severe respiratory distress,

Subtle neurologic dysfunction
Hyperactivity
Poor attention

hypothyroxinemia, postnatal corticosteroid exposure, and multiple gestation.[15,24,29,30] Despite these identified factors, most cerebral palsy cases, especially among term infants, do not have a readily identifiable cause. Protective factors could include maternal antenatal corticosteroid therapy, preeclampsia, and antenatal magnesium sulfate.[24,62] Although birth asphyxia has been identified as a frequent cause of cerebral palsy among term infants, low Apgar scores have correlated poorly with cerebral palsy for preterm infants.[21]

Epidemiologic studies of cerebral palsy rates have been hampered by disagreement over both the specific diagnostic criteria used and the age at which a diagnosis should be made. Most of the cases of cerebral palsy among preterm children pertain to children with spasticity rather than to the athetotic or dyskinetic types of cerebral palsy. These include the subtypes with bilateral (diplegia, quadriplegia) or unilateral (hemiplegia) spasticity. Diplegia and hemiplegia are the most common types of cerebral palsy seen in preterm children. Children with global hypotonia are usually not included in the diagnosis of cerebral palsy. Cerebral palsy was previously defined as mild, with no loss of function and independent walking; moderate, with functional disabilities requiring assistance for walking with aids or walkers; and severe, nonambulatory, requiring a wheelchair. Cerebral palsy was alternatively labeled *disabling* or *nondisabling* to incorporate a crude measure of functional impairment.[71] With the exception of these descriptive terms, there was no reliable measure of the severity of motor disability or consideration of other cognitive or neurosensory problems associated with cerebral palsy. In 2004, an international workshop on the definition and classification of cerebral palsy proposed inclusion not only of motor disorders but also of other associated deficits that may coexist, including seizures and cognitive, perceptual, sensory (visual and hearing), and behavioral impairments.[6] The 2004 classification also includes anatomic and radiologic findings and causation and timing of the lesion. Very few reports to date include this new definition. In the future, its use should improve the classification of children with cerebral palsy and facilitate studies of trends in the rates of cerebral palsy and its correlates.

The diagnosis of cerebral palsy is usually delayed until motor development has been established. The minimal age before a definitive diagnosis can be made should be at least 3 years and preferably 5 years of age. This is because in some cases, the neurologic findings may decrease or disappear by 5 years of age, and in other mild cases, the findings may only become apparent later.[67,86] The longest study of trends in the rates of cerebral palsy has been that of Hagberg and colleagues. They have monitored the rates in western Sweden in a series of nine reports from 1954 until the most recent period of 1995 to 1998.[45,48] During the 1950s, very few of the children with cerebral palsy in the western Swedish register were born before 28 weeks' gestation, whereas by 1995 to 1998, 20% to 25% of these children were born at this extremely low gestation, evidence of the increase in survival of these infants. Survival increased progressively during the periods of study. Overall, the prevalence of cerebral palsy among preterm infants decreased between the periods 1954 to 1958 and 1967 to 1970, partly owing to discontinuation of various iatrogenic therapies such as prolonged starvation and discontinuation of limitation of oxygen thought to cause retinopathy of prematurity. After the introduction of methods of neonatal intensive care and the increase in survival of infants of extremely low birthweight and gestation, the rates of cerebral palsy increased by 1987 to 1990, with an increase in cases with severe multiple handicaps. Similar trends were noted by others.[16] The prevalence then decreased significantly by 1995 to 1998 (Fig. 41-3). Most recently, several other reports have suggested similar decreases in the rates of cerebral palsy.[74,78,101]

Assessment of Functional Outcomes

One of the most widely used tools to classify gross motor function for children with cerebral palsy is the Gross Motor Function Classification System (GMFCS) introduced by Palisano.[7,70] This tool defines motor function on the basis of self-initiated movement with particular emphasis on sitting, walking, and mobility using a five-level classification system in which criteria meaningful to daily living distinguish the levels. Distinctions are based on functional limitations, the need for hand-held mobility devices such as walkers, crutches, or wheeled mobility,

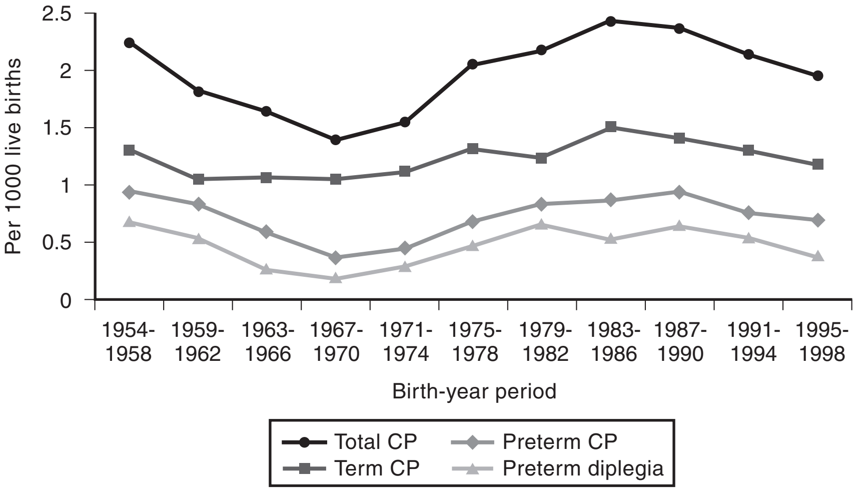

Figure 41–3. Crude prevalence of cerebral palsy (CP) per 1000 live births, 1954 to 1994. *(Data from Himmelmann K, et al: Changing panorama of cerebral palsy in Sweden. IX. Prevalence and origin in the birth year period 1995-98,* Acta Paediatr *94:287, 2005.)*

and to a much lesser extent, quality of movement. Because classification of motor function is dependent on age, separate descriptions are applied over a variety of age ranges. The focus of GMFCS is on determining which level best represents the child's present abilities and limitations. Emphasis is placed on usual performance in home, school, and community settings rather than on what the children can do as their best capability. An example of the classification system used for toddlers is presented in Figure 41-4.

Other measures used in examining functional outcomes include limitations in activities of daily living, such as difficulty feeding, dressing, and toileting, as well as the inability to play with other children. Most of these functions are applicable only after 2 years of age.

The functional measures of outcome that focus on the consequences of the various diverse medical, behavioral, and cognitive disorders resulting from prematurity are more suited for planning services for children with special health care needs.[82] Additional measures that can be used include the assessment of the overall health status of the child, the Child Health and Illness Profile, and the QUICCC (Questionnaire for Identifying Children with Chronic Conditions) and measures of the quality of life of the child.[56,79,87,88]

Children with a birthweight of less than 750 g or gestational age younger than 26 weeks have higher rates of functional limitations, greater compensatory dependence, and an increased need for services compared with those with a birthweight of greater than 750 g.[36,41] Recent data from Europe indicate that increased survival of infants with a birthweight of ≤750 g coincided with slightly greater impaired neurodevelopmental outcome at 2 years of age. Small-for-gestational-age infants are especially at risk.[15a] With the exception of a few children (3% to 5%) with severe disability, the major needs for services are those related to special education for the various academic learning and behavioral problems in school. Although reports by Saigal and associates and others note an acceptable quality of life for most adolescents and young adults who were born preterm, even for those with disability, educational and behavioral problems persist into adolescence and young adulthood.[10,79]

Timing of Follow-up Visits

The initial follow-up visit should be 7 to 10 days after discharge from the neonatal nursery. This is important for evaluating how the child is adapting to the home environment. A clinic visit at about 4 to 6 months of corrected age is important for documenting problems of inadequate catch-up growth and severe neurologic abnormality that might require intervention or occupational and physical therapy. Eight to 12 months of corrected age is a good time to identify the suspicion or presence of cerebral palsy or other neurologic abnormality. It also is an excellent time for the first developmental assessment to be performed, usually the Bayley Scales of Infant Development, because the children show little stranger anxiety at this age and are most cooperative.

By 18 to 24 months of age, most transient neurologic findings will have resolved, and the neurologically abnormal child will be showing some adaptation, with improving functional ability. Most potential catch-up growth will have occurred. At the same time, the cognitive and language scales of the Bayley Scales of Infant Development provide some assessment of the child's cognitive functioning.

At 3 years, other measures of cognitive function can be performed that better validate the child's mental abilities. Language is well measurable at this age. From 4 years of age, more subtle neurologic, visuomotor, and behavioral difficulties are measurable. These difficulties can affect school performance, even in children who have normal intelligence.[32,33,37,68]

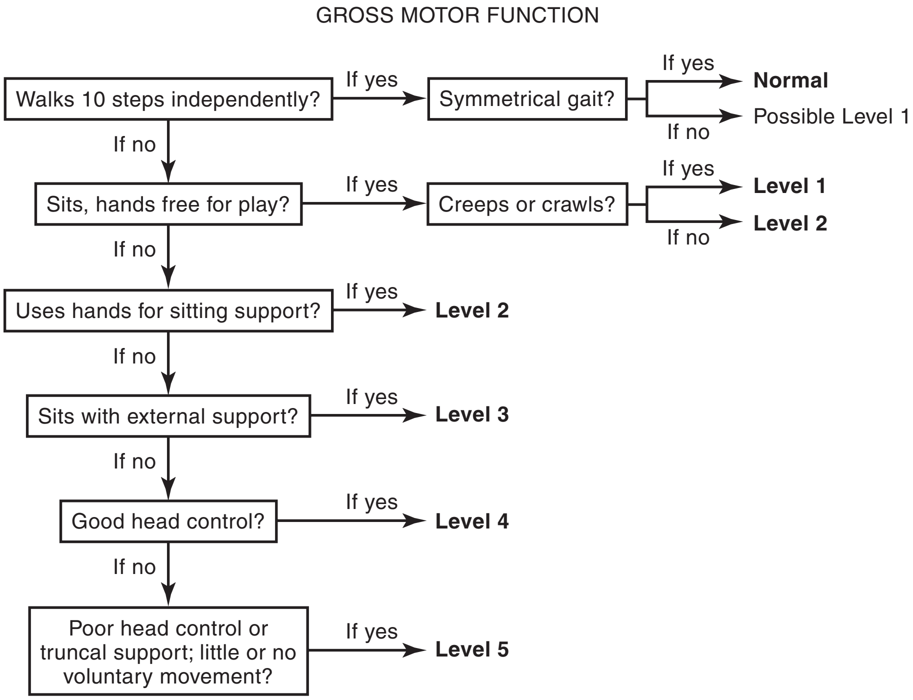

Figure 41–4. Gross motor function classification system for toddlers. *(Data from Palisano RJ, et al: Development and reliability of a system to classify gross motor function in children with cerebral palsy,* Dev Med Child Neurol *39: 214, 1997.)*

Developmental and Neurologic Testing

The neurologic examination during infancy is largely based on changes in muscle tone that occur during the first year of life. The examination developed by Amiel-Tison measures the progressive increase in active muscle tone (head control, back support, sitting, standing, walking) together with the concomitant decrease in passive muscle tone. This also documents visual and auditory responses and some primitive reflexes. This method gives a qualitative assessment of neurologic integrity, which is defined as normal, suspect, or abnormal. A conventional neurologic examination should be performed thereafter, together with the Amiel-Tison method for early childhood.[2,3]

The Bayley Scales of Infant Development is the most commonly used tool for monitoring early cognitive and motor development for high-risk infants. During the past 25 years, longitudinal follow-up programs have used this assessment tool to evaluate early outcomes. It is also used clinically to identify infants who might benefit from interventional services. The scales were developed for children aged 1 month to 3½ years of age. The first and second editions of the Bayley Scales were divided into three subtests or scales (mental, motor, and behavior) and provided a Mental Developmental Index and Psychomotor Developmental Index (PDI) with a mean of 100 and a standard deviation of 15. The Mental Development Index and Psychomotor Development Index scores have long served as useful tools for neonatal outcomes research. The 1992 revision yielded lower scores for survivors than those described for children born during the 1980s and early 1990s and tested with the original Bayley Scale.[102]

In 2006, the most recent iteration of the Bayley Scales, the third edition, was introduced. A major driving force for the revision was to provide additional scales to fulfill the requirements of federal and state mandates regarding five major areas of development for early childhood assessment from birth through 3 years of age. As a result, the newest version contains five scales: cognitive, language, motor, social-emotional, and adaptive behavior, the latter two in the form of parent questionnaires. Thus, the third edition of the Bayley Scale does not generate a “mental developmental index” but rather separate cognitive and language scores. Preliminary evaluations have suggested improved early cognitive outcomes for preterm infants using the third edition of the Bayley Scale.

It is not clear that infant tests measure the same constructs as intelligence tests that are administered to older children and adults. Infant tests are seen as a description of current functioning and thus are not predictive. Generally, infant tests have not been shown to have long-term validity, especially for some clinical subgroups. The poor prediction is considered to result from difficulties in infant testing, measurement error, changes in function of the child, and environmental influences that become more evident after 2 years of age. Several recent studies of children with extremely low birthweight have reported significantly lower rates of intellectual impairment at school age than during early childhood.[40,98]

The Ages and Stages Questionnaire may be used as a screening tool for children aged 3 months to 5 years to identify developmental delays.[14] The tool uses parents as the source of information about child development and has been successful in identifying cognitive and motor delays in the follow-up of premature infants and those with hypoxic ischemic encephalopathy.[57,83] However, it does not give a quantitative assessment and thus cannot be used to quantify outcome in specific high-risk populations. The Wechsler Scales may be used with prekindergarten and school-age children. The Wechsler Intelligence Scale for Children, third edition, is probably the most commonly used instrument for school-age assessment. The Kaufman Test was standardized on a 2½- to 10-year-old population and is less heavily weighted by verbal items than other tests.

Ophthalmologic testing should be performed in all high-risk children (see Chapter 53). If the results are abnormal, repeat examinations should be done at the discretion of the ophthalmologist. All children should have a repeat eye examination between 12 and 24 months of age (see Chapter 53, Part 3, for specific examination timetables).

Hearing should be screened before discharge from the neonatal intensive care nursery. Most hearing screening programs use the otoacoustic emissions test, in which a small earphone and microphone are inserted into the infant’s ears. When sounds are played, a normally functioning ear will create an echo that can be picked up by the microphone. In a baby with hearing loss, no echo can be detected. Otoacoustic emissions can reliably detect hearing losses above 1500 Hz, but only in the presence of outer hair cell dysfunction. Auditory brainstem response testing may be used for infants who fail the initial hearing screen. The auditory brainstem response test uses electrodes to detect brainwaves. As sounds are played, the test measures the brain’s response. The test can detect improper functioning in the inner ear, acoustic nerve, and auditory brainstem pathways associated with hearing. It can detect hearing sensitivity from 1000 to 8000 Hz (see Chapter 42). Hearing should be reexamined at 12 to 24 months because hearing loss can appear later as a sequela of ototoxic drugs such as diuretics. In addition, late-onset hearing loss can occur secondary to cytomegalovirus infection in the newborn period. Hearing loss related to middle ear infections can also occur after the neonatal period and during the first 2 years of life.

SCHOOL-AGE OUTCOME

Measuring school-age outcomes is an important landmark in longitudinal follow-up. Most of the school-age outcome studies of very premature children have compared these premature survivors with children of normal birthweight, documenting significantly more major and subtle neurologic dysfunction, lower intelligence, poorer performance on tests of language and academic achievement, and more behavioral difficulties than control groups of children with normal birthweight who have similar race, gender, and sociodemographic backgrounds.[4,5,35] When only those children with normal intelligence who are free of major neurologic impairment are considered, some of these differences disappear. However, significant differences in tests of visuomotor function and mathematics continue.[93] There also are behavioral differences that interfere with the child’s attention and ability to complete a task (Fig. 41-5).[9,43]

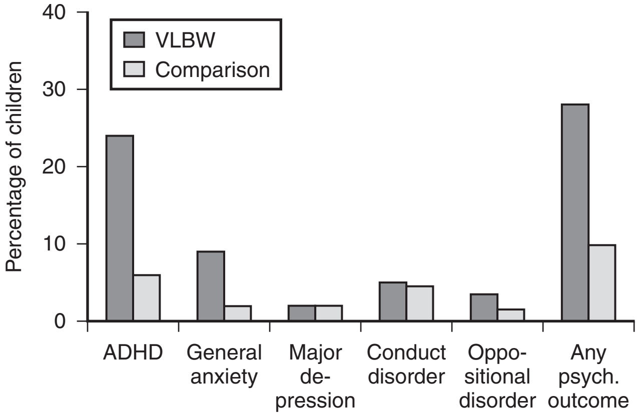

Figure 41–5. Psychiatric (psych.) outcomes in adolescent children who had very low birth-weight (VLBW). ADHD, attention deficit hyperactivity disorder. *(Data from Botting N, et al: Attention deficit hyperactivity disorders and other psychiatric outcomes in very low birthweight children at 12 years,* J Child Psychol Psychiatry *38:931, 1997.)*

Few studies have compared school-age outcomes among premature infants over time. One study comparing survivors of very low birthweight born in the early 1980s with those born in the mid-1990s suggests that, despite improved survival rates, mean intelligence scores did not differ.[46] Another study of survivors at 8 years of age documents lower rates of disability for children with extremely low birthweight born in the 1990s compared with the early 1980s.[23]

In terms of their overall health status, extremely preterm children have many more functional limitations and compensatory dependency needs and require many more services above routine than term-born children.[41] These differences persist even when children with neurosensory impairments are excluded. Although most children with very low birthweight remain in the regular school system, many have difficulty coping with the demands of school learning and require more special education and remedial therapy.[68,103] The problems that appear to be most related to academic success in addition to cognition fall within the psychological and psychiatric domains and include deficits in attention, memory, and behavior. Most preterm children who are free from major disability are functioning within the low-normal range on intelligence quotient tests. Sociodemographic and environmental factors may contribute more to the differences in cognitive outcomes than biologic risk factors, with social risks becoming more pronounced as the children age. Structural brain abnormalities detected by magnetic resonance imaging and involving the lateral ventricles, corpus callosum, and white matter are more common among preterm survivors than among controls. These findings provide an anatomic basis for these neurodevelopmental problems.[90]

YOUNG ADULT OUTCOMES

Information on the young adult outcomes of the initial survivors of neonatal intensive care has now been reported from around the developed world.* The studies have differed with regard to whether they were regional or hospital based and the birthweight group, rate of survival, sociodemographic status, and types of outcome studied. Despite these differences, the overall results suggest that neurodevelopmental and growth sequelae of prematurity persist into young adulthood. Traditionally, educational attainment, employment, independent living, marriage, and parenthood have been considered as markers of successful transition to adulthood. When compared with controls with normal birthweight, young adults with very low birthweight have poorer educational achievement, more chronic illnesses such as asthma or cerebral palsy, and less physical activity.[42] Higher rates of obesity among females have also been reported. In terms of brain structure, diffuse abnormalities including reduction in gray and white matter volume, increased ventricular volume, thinning of the corpus callosum, and periventricular gliosis have all been reported among young adults born prematurely.[1,26,84] The impact of these structural differences on brain function is uncertain; however, cognitive and behavioral differences have been reported. In general, young adults with very low birthweight report less risk taking. Fewer females born at very low birthweight have ever dated or been involved in an intimate relationship. In addition, pregnancy and childbirth rates are lower for young women with very low birthweight. Alcohol and marijuana use also tend to be less prevalent among the former preterm adults.[38,42] Although the information varies, there is currently no clear evidence of an increase in attention deficit hyperactivity disorder or psychosis among adult preterm survivors. However, there is some evidence for an increase in anxious, withdrawn, and depressed symptoms, predominantly among women. This may affect both the development of adult social interactions and the formation of permanent relationships and predispose to further psychopathology later in life.[12,39,44]

The adult outcomes described to date pertain mainly to preterm infants born in the 1970s and early 1980s, a time when neonatal mortality was high and few extremely immature infants survived. Despite statistically significant differences in most outcomes measured, including educational achievement, health status, and socialization, most preterm survivors born during the early years of neonatal intensive care do well and live fairly normal lives. In fact, studies have demonstrated similar self-esteem, overall health satisfaction, and quality of life compared with adults with normal birthweight.[17,80,95,108]

Researchers in Sweden and Norway have recently used their excellent national longitudinal databases to examine the adult outcomes over the complete spectrum of gestational age, ranging from 23 weeks to term gestation, thus allowing for the examination of the relative outcomes of extremely preterm, late preterm, and term-born children.[58,60,65,91] These national studies, which link birth data to later outcomes, also have the advantage of including all the subjects of interest with very little loss to follow-up. Outcomes reported from these national databases pertain to health, functional, educational, and developmental outcomes of importance to society, but provide very little in depth analyses of the correlates and predictors of specific outcomes. The two major predictors of adult outcomes are lower gestational age, which reflects perinatal injury, and family sociodemographic status, which reflects both genetic and environmental effects.

CHILDREN BORN AT THE THRESHOLD OF VIABILITY

With advanced perinatal care, survival at a birthweight of less than 750 g increased from 32% to 46% in the early 1990s to 55% to 67% more recently.[25,49,50,89] Evaluating the outcomes of these infants born at the threshold of viability raises one of the most difficult problems for obstetricians and pediatricians. Published outcome reports derive from a range of populations including those from single tertiary centers with selected patients and others based on geographically defined areas. Furthermore, survival and morbidity are defined differently in different studies and show wide variation. Outcome data by gestational age are sparse and exquisitely dependent on many other covariables. For example, a recent evaluation of 2-year outcomes for infants enrolled in the Neonatal Research Network of the National Institute of Child Health and Human Development and born between 22 and 25 weeks' gestation reported a 51% survival rate, with 61% experiencing death or profound impairment. In multivariable analyses, exposure to antenatal corticosteroids, female sex, singleton birth, and a higher birthweight were each associated with reductions in the risk for death or profound impairment, similar to those associated with a 1-week increase in gestational age.[97]

The largest population-based study of infants born between 20 and 25 weeks' gestation is the EPICure study from the United Kingdom and Ireland. The major morbidities influencing later development included chronic lung disease, severe brain injury, and severe retinopathy of prematurity.[18] In addition to severe brain insult and chronic lung disease, factors reported to correlate with later poor outcome include male sex, maternal chorioamnionitis, postnatal steroid exposure, neonatal sepsis, transient hypothyroxinemia, and jaundice.[37,69,77,93,100,106]

School-age follow-up of the EPICure cohort at 6 years revealed cognitive impairment in 21% of the children, severe disability in 22%, and disabling cerebral palsy in 12%.[61] In terms of overall function, the EPICure children demonstrated school difficulties, language problems, poor respiratory health, and a variety of pervasive behavioral problems, including attention deficit, hyperactivity, and social-emotional problems.[47,81,104] At age 11 years, the EPICure survivors continued to demonstrate cognitive impairment with specific problems in reading and mathematics. Fifty-seven percent required special educational services.[54] Similar results have been reported at school age for a regional cohort of children born weighing less than 1000 g or before 28 weeks' gestation in Australia.[4,19]

A review of the world literature on survivors of a birthweight of less than 750 g or before 26 weeks' gestation reveals that during early childhood, the rates of severe neurosensory disability range from 9% to 37%, with cerebral palsy occurring in 5% to 37%, blindness in 2% to 25%, and deafness in 0% to 7%. Subnormal cognitive function is noted in 15% to 47% of survivors.[36] This population of children thus represents a subgroup of preterm children who are at the highest risk for poor school performance.

EARLY INTERVENTION

In response to the concern for the adverse developmental and scholastic outcomes among preterm infants, the Infant Health and Development Program undertook a multicenter randomized trial to assess the benefit of a comprehensive early intervention program. The program, which provided intensive educational enrichment to preterm infants with low birthweight, improved the intelligence quotient scores of the children at 3 years of age; however, children of the lowest birthweight ($<$1000 g) and thus at greater biologic risk were less responsive to the intervention.[51] Subsequent follow-up of the cohort at age 8 years demonstrated only minimal effects of the intervention on cognitive status, school achievement, or behavior.[63] Additional studies of the impact of early intervention on childhood outcomes have yielded mixed results.[28,53,55,107] A meta-analysis of 16 studies, including 6 randomized controlled trials of early intervention programs, suggests improved cognitive outcomes in infancy and preschool, but no significant impact at school age.[85] Recently, the late adolescent outcomes of children enrolled in the Infant Health and Development Program were reported, suggesting slight improvements in mathematics, vocabulary, and behavior among those who received early intervention; however, these improvements were noted only among the larger preterm children.[64] Physical and occupational therapy have not been shown in randomized, controlled trials to significantly improve outcomes. Despite these findings, early intervention programs can provide educational support to parents and are considered beneficial, especially for children from deprived homes.

CHAPTER 42

Hearing Loss in the Newborn Infant

Betty Vohr

BACKGROUND

Tremendous progress has been made during the past 15 years in the identification of hearing loss in newborns. The National Institutes of Health issued a "Consensus Statement on Early Identification of Hearing Impairment in Infants and Young Children in 1993."[33] The statement concluded that all infants admitted to the neonatal intensive care unit (NICU) should be screened for hearing loss before hospital discharge and that universal hearing screening should be implemented for all infants within the first 3 months of life. At the time of the National Institutes of Health consensus statement, only 11 hospitals in the United States were screening more than 90% of their newborn infants. In the United States, the percentage of infants screened for hearing loss increased significantly from 46% in 1999 to 93% in 2006.[10]

The percentage of infants who fail the screening process is about 2.1% (range, 0.3% to 6.5%), and rates of permanent hearing loss subsequently diagnosed by comprehensive audiology testing range from 1 to 3 per 1000, making congenital hearing loss the most common birth defect diagnosed as a result of the newborn screening process.[10] Undetected, hearing loss negatively affects communication development, academic achievement, literacy, and social and emotional development,[28,29] whereas early identification and intervention, particularly within the first 6 months of life, clearly provide benefit for communication development in infants.[50] There is accumulating evidence that the brain may be optimally responsive to language input early in life.[42,43]

Based on these findings, the Joint Committee on Infant Hearing 2000 and 2007 Position statements[21,22] published the 1-3-6 recommendation to maximize the outcomes of infants with all degrees of hearing loss: All infants should be screened for hearing loss no later than 1 month of age, and infants who do not pass the screen should have a comprehensive evaluation by an audiologist no later than 3 months of age for confirmation of hearing status. Infants with confirmed hearing loss should receive appropriate intervention no later than 6 months of age from professionals with expertise in hearing loss and deafness in infants and young children.

NORMAL HEARING AND HEARING LOSS

The ear consists of outer, middle, and inner components. The external ear includes the pinna and the outer ear canal. Sounds waves travel through the air and are conducted through the outer ear canal to the tympanic membrane, where vibrations enter the middle ear and are amplified and transmitted through the ossicles to the fluid within the cochlea (inner ear). Sound waves in the inner ear are transmitted through the fluid and stimulate both the outer and inner hair cells of the cochlea. The outer hair cells respond to sound energy by producing an echo of sounds called *otoacoustic emissions*, and the inner hair cells act by converting mechanical energy into electrical energy transmitted to the cochlear branch of the eighth cranial nerve, the brainstem, and finally the auditory cortex for perception of the meaning of sounds. In normal hearing individuals, all components of the pathway are intact and functioning. Blockage of sound conduction in the outer or middle ear may result in either a transient (fluid or debris) or permanent (anatomic abnormality such as atresia or microtia) conductive hearing loss. Failure of sound transmission within the cochlea, outer and inner hair cells, and eighth cranial nerve are a manifestation of sensorineural hearing loss, whereas pathology of the inner hair cells and eighth cranial nerve with intact outer hair cells is characteristic of neural hearing loss, also referred to as *auditory neuropathy* or *auditory dyssynchrony*.

Hearing loss can be classified as bilateral or unilateral and as mild, moderate, severe, or profound. The types of hearing loss that can be identified at birth are shown in Table 42-1. Types of permanent hearing loss that can be identified with newborn screening include sensorineural, neural, and conductive. Transient conductive hearing loss may also be present, especially in infants who have been hospitalized in an

TABLE 42–1 Types of Hearing Loss

Type	Characteristics
Sensorineural	Pathology involving cranial nerve VIII and outer hair cells and inner hair cells of the cochlea that impairs neuroconduction of sound energy to the brainstem
Permanent conductive	Anatomic obstruction of the outer ear (atresia) or middle ear (fusion of ossicles) that blocks transmission of sound
Neural or auditory neuropathy or auditory dyssynchrony	Pathology of the myelinated fibers of cranial nerve VIII or the inner hair cells that impairs neuroconduction of sound energy to the brainstem. The function of the outer hair cells remains intact.
Transient conductive	Debris in the ear canal or fluid in the middle ear that blocks the passage of sound waves to the inner ear
Mixed hearing loss	A combination of sensorineural or neural hearing loss with transient or permanent conductive hearing loss

NICU. Mixed hearing loss is a combination of permanent hearing loss and transient conductive hearing loss.

TESTS FOR HEARING LOSS

Screening and hearing diagnostic tests are shown in Table 42-2. Physiologic tests include those that measure electrical activity or reflexes and include OAE and auditory brainstem response (ABR) testing. These tests do not require an active response from the infant and can be performed when asleep. OAE screen measurements are obtained using a sensitive microphone within a probe inserted into the ear canal that records the sound produced by the outer hair cells of a normal cochlea in response to a sound stimulus. Abnormal outer and middle ear function due to blockage or background noise may interfere with recording OAEs. Automated auditory brainstem response (AABR) for screening and ABR for diagnostic testing are obtained from surface electrodes that record neural activity in the cochlea, outer and inner hair cells, auditory nerve, and brainstem in response to a click stimulus. In AABR, a predetermined algorithm provides an automated pass-or-fail response to the presence or absence of wave 5 on the ABR. Both OAE and ABR detect sensorineural and conductive hearing loss. A false-positive fail screen for permanent hearing loss may result from outer or middle ear dysfunction, including the presence of a transient conductive hearing loss (fluid or debris) or noise interference. OAEs cannot be used to screen for neural hearing loss because pathology in this disorder involves the inner hair cells, eighth cranial nerve, and brainstem with intact outer hair cells. Infants with neural hearing loss will therefore fail ABR but pass OAE. The Joint Committee on Infant Hearing 2007 states that infants cared for in the NICU for greater than 5 days are at highest risk for neural hearing loss and therefore should only be screened with AABR.[22] Some hospitals use a two-step screen with both AABR and OAE.

Tympanometry (immittance) testing is used to assess the peripheral auditory system, including the function, intactness, and mobility of the tympanic membrane, the pressure in the middle ear, and the mobility of the middle ear ossicles. A probe is placed in the inner ear, and air pressure is changed to assess the movement of the tympanic membrane. The tympanogram shows the response of the tympanic membrane in response to the pressure stimulus: a type A curve is considered a normal response. A completely flat response may be reflective of fluid in the middle ear or perforation of the tympanic membrane. Tympanometry is not used for screening.

Behavioral tests include vision reinforcement audiometry (VRA), which is appropriate for rested alert infants with a developmental age of at least 6 months. The infant must have the functional capability of turning to sounds. For administration of VRA, the infant sits on the mother’s lap in a sound booth, earphones are inserted, and the infant is conditioned to turn to sounds that are paired to animated toys that appear either to the right or left side. Traditional behavioral testing is used for toddlers at least 2½ years of age. Children respond by placing a block in a box each time they hear a sound.

For confirmation of an infant’s hearing status, a test battery is required to cross-check results of both the physiologic measures and the behavioral measures.[19] The purposes of the audiologic test battery are to assess the integrity of the auditory system, to estimate hearing sensitivity across the frequency range, and to determine the type of loss. Infants who fail a newborn screen should have a diagnostic assessment as soon as possible after the newborn screen and not later than 3 months of age.

EARLY INTERVENTION SERVICES

There is a body of evidence supporting the importance of early enrollment in early intervention services to improve the outcomes of children with hearing loss. Before universal hearing screening, children with severe to profound hearing loss were identified at 24 to 30 months of age and subsequently demonstrated significant delays in communication, language, and literacy.[28,29] The Colorado study first reported that children with hearing loss who received intervention services before 6 months of age had speaking, sign, or total communication language scores comparable with hearing children at 3 years of age.[50] A second report demonstrated that at 12 months, children with hearing loss who were enrolled in early intervention at 3 months or younger had

TABLE 42–2 Tests for Hearing Screening and Diagnosis

Test	Mechanism	Type of Hearing Loss Detected
Otoacoustic emissions (OAE) screen	OAE tests represent a response of the outer hair cells in the cochlea to a sound stimulus; the hair cells produce echo-like responses that can be detected and recorded with a high-sensitivity microphone. Automated equipment is available.	Sensorineural Conductive
Automated auditory brainstem response screen	Automated auditory brainstem response screen tests based on threshold algorithms have become standard for screening.	Sensorineural Conductive Neural
The following physiologic and behavioral tests are used as part of a diagnostic battery:		
Auditory brainstem response diagnostic	Auditory brainstem response potentials are a reflection of electrical activity in cranial nerve VIII and auditory brainstem pathway that can be detected with scalp electrodes to produce an auditory brainstem response.	Sensorineural Conductive Neural
Tympanometry battery	This measure of middle ear function is part of the battery for all children. For infants younger than 6 months, a high-frequency probe tone of 1000 Hz is indicated.	Conductive
Vision reinforcement audiometry (>6 months of age) Conditioned audiometry response (>2.5 years of age)	Observations of the infant's behavioral responses to sounds	Sensorineural Conductive Neural
Standard audiometry (>4.5 years of age)	Observation of the child's behavioral responses to a task in response to sounds	Sensorineural Conductive Neural

significantly higher scores for number of words understood, words produced, early gestures, later gestures, and total gestures compared with children enrolled after 3 months of age.[49] The Joint Committee on Infant Hearing 2007 recommends that infants with all degrees of unilateral or bilateral hearing loss need to be referred to Early Intervention Services at the time of diagnosis and receive services no later than 6 months of age. These services should be provided by professionals who have expertise in hearing loss, including educators of the deaf, speech-language pathologists, and audiologists.

ETIOLOGY OF HEARING LOSS

It is estimated that at least 50% of congenital hearing loss is hereditary. Nearly 400 syndromes and hundreds of genes associated with hearing loss have been identified.[9,18,31,32] Genetic hearing loss is about 30% syndromic and 70% nonsyndromic. Among children with nonsyndromic hearing loss, 75% to 85% of cases are autosomal recessive *(DFNB)*, 15% to 24% are autosomal dominant *(DFNA)*, and 1% to 2% are X-linked *(DNF)*. Therefore, most infants with hearing loss have nonsyndromic autosomal recessive hearing loss and are born to hearing parents. A single gene, *GJB2*, which encodes connexin 26, a gap-junction protein expressed in the connective tissues of the cochlea, accounts for up to 50% of all cases of profound nonsyndromic hearing loss. More than 100 mutations of *GJB2* have been identified. A single *GJB2* mutation, 35delG, accounts for up to 70% of the mutations. The etiology of hearing loss will be reviewed relative to the risk factors for hearing loss published by the Joint Committee on Infant Hearing 2007 (Box 42-1).

RISK FACTORS

The first two risk factors are obtained by parent report. Parents may not be aware of a family history of hearing loss or of syndromes associated with hearing loss until discussing the possibility with relatives. If a family history of hearing loss is reported for an infant who passes the screen, ongoing surveillance is indicated with at least one follow-up audiologic assessment by 24 to 30 months of age. All families with an infant with hearing loss, regardless of family history of hearing loss, will benefit from a genetics consultation. Risk factor 2, caregiver concern regarding hearing, speech, language, or developmental delay in the first 2 to 3 years of life,[37] has also been shown to be associated with an increased risk for late-onset or progressive hearing loss not detected in a newborn screen. It is important to remember that the rate of hearing loss doubles between birth and school age

BOX 42–1 **Risk Factors Associated with Permanent Congenital, Delayed Onset, or Progressive Hearing Loss**

1. Caregiver concerns* regarding hearing, speech, language, or developmental delay
2. Family history of permanent hearing loss*
3. Neonatal intensive care for >5 days, including any of the following: extracorporeal membrane oxygenation,* assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide, Lasix), and, regardless of length of stay, hyperbilirubinemia requiring exchange transfusion
4. In utero infections, such as cytomegalovirus,* herpesvirus, rubella, syphilis, and toxoplasmosis
5. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies
6. Physical findings, such as white forelock, that are associated with syndromes known to include a sensorineural or permanent conductive hearing loss
7. Syndromes associated with hearing loss or progressive or late-onset hearing loss,* such as neurofibromatosis, osteopetrosis, and Usher syndrome. Other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson syndromes.
8. Neurodegenerative disorders* such as Hunter syndrome or sensory motor neuropathies such as Friedrich ataxia or Charcot-Marie-Tooth disease
9. Culture-positive postnatal infections* associated with sensory neural hearing loss including confirmed bacterial and viral (especially herpesviruses and varicella) meningitis
10. Head trauma, especially basal skull or temporal bone fracture, that requires hospitalization
11. Chemotherapy*

---

*Risk factors that are of greater risk for delayed onset or progressive hearing loss.

from 2 to 3 per 1000 in newborns to about 7 per 1000 at school age,[20] and, therefore, caregiver concern should prompt a referral for further evaluation.

Medical complications are associated with 40% of childhood permanent hearing loss. Risk factor 3 includes infants requiring neonatal intensive care for greater than 5 days, *and any of the following morbidities regardless of length of stay*: extracorporeal membrane oxygenation, assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide or Lasix), and hyperbilirubinemia requiring exchange transfusion.[14,37,38] Risk factor 4 includes in utero infections such as cytomegalovirus, herpes, rubella, syphilis, and toxoplasmosis.[14-16,26,32,36] Cytomegalovirus remains the most common medical cause of both early- and delayed-onset hearing loss in infants and children.[16] Most infants with congenital cytomegalovirus infection have no clinical findings at birth, and the diagnosis goes unrecognized.

Risk factors 5 to 8 are all associated with congenital abnormalities or syndromes. Risk factor 5 includes craniofacial anomalies, such as those involving the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies.[11] These defects are common in both the well-baby nursery and the NICU. Many of these findings reflect abnormalities in the embryologic development of the ear. The external ear, middle ear, and eustachian tube develop from the branchial apparatus beginning at the fourth week of gestation. The pinna arises from the coalescence of the first and second arch tissues of the first branchial cleft, which will become the external auditory canal. The eustachian tube and middle ear space develop from the first pharyngeal pouch, and the ossicles from the mesoderm of the first and second arches. The inner ear develops from surface ectoderm and neuroectoderm beginning in the third week of gestation, with the cochlea, semicircular canals, utricle, and saccule formed by 15 weeks. The inner ear reaches adult size by 23 weeks. Risk factor 6 includes visible physical findings such as white forelock, which is associated with Waardenburg syndrome.

Risk factor 7 includes syndromes associated with hearing loss or progressive or late-onset hearing loss such as neurofibromatosis, osteopetrosis, and Usher syndrome.[38] Usher syndrome is the most common cause of autosomal recessive syndromic hearing loss (4% to 6% of children with hearing loss). Affected individuals develop vestibular problems secondary to progressive retinitis pigmentosa and become blind with increasing age. Subtypes are associated with either mild to severe or severe to profound hearing loss. Early diagnosis is critical because a visual means of communication is not an option for a child who will become blind with increasing age. Other frequently identified syndromes include Waardenburg, Pendred, Jervell and Lange-Nielson, and Alport syndromes.[31] The most common autosomal dominant syndrome is Waardenburg syndrome. It occurs in 1% to 4% of children with hearing loss. Children have sensorineural or permanent conductive hearing loss and associated heterochromia iridis. Pendred syndrome is the second most common autosomal recessive cause of syndromic hearing loss. It is characterized by severe to profound hearing loss and euthyroid goiter, which presents during adolescence or later. An abnormality called Mondini dysplasia or dilated vestibular aqueduct, which is diagnosed by computed tomography examination of the temporal bones, is associated with Pendred syndrome. Jervell and Lange-Nielson syndrome is characterized by prolongation of the QT segment on electrocardiogram and is associated with sudden infant death and syncope. Children with QT prolongation should be seen in consultation by cardiology for management. Branchio-otorenal syndrome is autosomal dominant and occurs in 2% of hearing loss. It is characterized by preauricular pits, malformed pinnae, branchial fistulas, and renal anomalies. Alport syndrome is X-linked or autosomal recessive, occurs in 1% of children with hearing loss, and is associated with progressive hearing loss

Risk factor 8 consists of neurodegenerative disorders such as Hunter syndrome or sensory motor neuropathies such as Friedreich ataxia and Charcot-Marie-Tooth syndrome.[38]

Risk factor 9 is culture-positive postnatal infections and includes confirmed bacterial and viral (especially herpesviruses and varicella virus) meningitis. Meningitis is associated with an increased incidence of sensorineural hearing loss.[3,6,7,38]

Risk factors 10 and 11 are risk factors encountered after discharge. Serious head trauma, especially basal skull or temporal bone fractures requiring hospitalization, is a risk factor for hearing loss in childhood.[25,51] Although rare in children, chemotherapy for leukemia or cancer remains a risk factor, which in some cases is reversible.[5] Box 42-1 identifies the risk factors associated with delayed-onset hearing loss. Although all children with a risk factor should have at least one follow-up visit with an audiologist, children with increased risk for delayed-onset hearing loss may require more frequent assessments.

MEDICAL WORKUP FOR HEARING LOSS AND CARE COORDINATION

A physician visit should be scheduled with the family as soon as a diagnosis of hearing loss is made to discuss the audiologist's report, provide information on community resources, and provide support for the family during a period of stress. During the postdiagnosis appointment with the family, the physician reviews the pregnancy, neonatal, and family history for hearing loss, reexamines the child for evidence of any craniofacial abnormalities or a syndrome associated with hearing loss, and discusses the benefits of early intervention services and amplification. The primary care physician, therefore, needs to be aware of community resources and support the family choice of early intervention program and mode of communication.

Every infant with confirmed hearing loss should be evaluated by an otolaryngologist with knowledge of pediatric hearing loss. The otolaryngologist conducts a comprehensive assessment to determine the etiology of hearing loss and provides recommendations and information to the family, audiologist, and primary care provider on candidacy for amplification, assistive devices, and surgical intervention, including reconstruction, bone-anchored hearing aids, and cochlear implantation.

Because of the prevalence of hereditary hearing loss, all families of children with confirmed hearing loss should be offered a genetics evaluation and counseling. This evaluation can provide families with information on etiology, prognosis, associated disorders, and the likelihood of hearing loss in future offspring. The geneticist will review the family history for specific genetic disorders or syndromes, examine the child, and complete genetic testing for syndromes or gene mutations for nonsyndromic hearing loss such as *GJB2* (connexin 26).[41]

Additional referrals may be made at that time for a developmental assessment or other indicated specialty evaluation. Because 30% to 40% of children with confirmed hearing loss have comorbidities or other disabilities, the primary care physician should closely monitor developmental milestones and initiate referrals related to suspected disabilities as needed.[23] Because of the association of hearing loss with vision impairments and the importance of vision for children with hearing loss, it is recommended that each child with a permanent hearing loss have at least one examination to assess visual acuity by an ophthalmologist experienced in evaluating infants.

MIDDLE EAR DISEASE

Otitis media with effusion (OME) is highly prevalent among young children, and about 90% of children have an episode of OME before starting school.[45] Middle ear status should be monitored closely in children with permanent hearing loss because the presence of middle ear effusion can further compromise hearing. Recommendations related to diagnosis of OME include examination with a pneumatic otoscope and documentation of laterality, duration of effusion, and severity of symptoms. Although about 40% to 50% of children with OME do not have symptoms,[39] some children may have associated balance problems.[17] Medical management of OME in children with permanent hearing loss may include hearing testing, amplification adjustment, and tympanostomy tubes. Most OME is self-limited,[40] and 75% to 90% of cases spontaneously resolve in 3 months. Therefore, a 3-month period of observation is recommended. Evidence suggests that no benefit is derived from the use of antihistamines or decongestants in children.

Children with persistent OME ($\geq$4 months' duration) with associated persistent hearing loss or structural injury to the tympanic membrane or middle ear become candidates for surgical intervention with tympanostomy. Tympanostomy has been shown to be associated with decreases in middle ear effusion and improved hearing.

COMMUNICATION OPTIONS

One of the important decisions that the family needs to make for the child is the communication mode that will work optimally for the child and family. There are five options. Auditory oral communication encourages the use of residual hearing and amplification with visual support (speech reading), and the goal is spoken language. Auditory verbal communication is based on listening skills alone, and the goal is spoken language. Cued speech uses a visual communication system that combines listening with eight hand shapes in four placements near the face and supports spoken language. Total communication combines all means of communication and encourages simultaneous use of speech and sign. Deaf children learn American Sign Language, and English is learned as a second language once American Sign Language is mastered. The choice of communication option for the family may change over time depending on the progress of the child and the degree of hearing loss. For example, for an infant born with a profound hearing loss, the family may initially choose total communication but, after a cochlear implant at 12 months of age, may use predominantly auditory verbal or auditory oral communication.

HEARING AIDS, FREQUENCY MODULATED SYSTEMS, AND COCHLEAR IMPLANTS

Hearing Aids

Hearing aids are compact and worn either in-the-ear (ITE) or behind-the-ear (BTE), and can be fitted on an infant in the first month of life. The main components are the microphone that picks up sounds and the amplifier. The audiologist uses computer programming to adjust the sound for an individual child's needs. If the child has different degrees of hearing loss at different frequencies, the audiologist adjusts the gain (loudness) by frequency. Normal speech range is from 500 to 2000 Hz. Ear molds are made from an impression of the child's ear. As a young infant grows, the ear molds may need to be replaced every 6-8 weeks.

Frequency Modulated Systems

Frequency modulated (FM) systems were developed for individuals with hearing loss to hear better in noisy environments. An FM system consists of a microphone and a receiver. A small radio transmitter is attached to a microphone and a small radio receiver. A parent or teacher wears the FM transmitter and microphone while the child wears the FM receiver. The FM transmitter sends a low-power radio signal to the FM receiver that needs to be within 50 feet of the transmitter. The FM receiver gets the signal from the microphone and sends it to a personal hearing aid or cochlear implant. Listening to the FM signal is similar to listening to speech only inches away. FM systems can be used in a variety of situations, including in the home, while shopping, or at school.

Cochlear Implants

According to the U.S. Food and Drug Administration, 30,000 children in the United Sates had received cochlear implants by the end of 2009. Candidacy criteria for pediatric cochlear implantation currently is 18 months or older for children with severe to profound bilateral sensorineural hearing loss and 12 to 18 months for children with profound hearing loss. In cases of deafness due to meningitis, implants may be placed early in the first year of life. A lack of benefit in the development of auditory skills with amplification needs to be demonstrated for eligibility for an implant. Children up to 7 years of age appear to derive the greatest benefit from a cochlear implant for the development of speech.[44]

Because of an increased risk for bacterial meningitis, it is recommended that physicians monitor all patients with cochlear implants, particularly children whose implants have a positioner,[7,34] for middle ear and other infections. *Streptococcus pneumoniae* is the most common pathogen causing meningitis in cochlear implant recipients.[27,46] All children with cochlear implants should be vaccinated according to the American Academy of Pediatrics high-risk schedule.

CONTINUED SURVEILLANCE

The Joint Committee on Infant Hearing 2007[22] has new recommendations for ongoing surveillance in the medical home for all infants with and without risk factors for hearing loss. Regular surveillance of developmental milestones, auditory skills, parental concerns, and middle ear status should be performed in the medical home, consistent with the American Academy of Pediatrics periodicity schedule.[2] All infants should have an objective standardized screen of global development with a validated screening tool at 9, 18, and 24 to 30 months of age or at any time if the health care professional or family has concern.[22] Language screens that can be used in the primary care setting include the Early Language Milestone Scale,[12] the MacArthur Communicative Development Inventory,[13] the Language Development Survey,[35] and Ages and Stages.[8]

Infants who do not pass the speech-language portion of a global screening or for whom there is a concern regarding hearing or language should be referred for speech-language evaluation and audiology assessment. This recommendation was implemented because of the known increase in the number of children identified with hearing loss between the newborn screen and school age. This is related to three factors: mild hearing loss is missed with newborn screening tools, there is delayed onset or progressive hearing loss such as that associated with cytomegalovirus, and there is late-onset hearing loss secondary to trauma or chemotherapy. Infants with OME may have transient hearing loss and associated language delays.

STRESS AND IMPACT ON THE FAMILY

Parents perceive varying degrees of stress when they are informed that their infant has failed a newborn hearing screen. Although the screen result may be either a false-positive or a true fail, most parents will have some increase in worry until their infant is rescreened. NICU infants have higher false-positive rates and higher fail rates than well-baby nursery infants. In one study[47] of well-baby nursery infants, parents reported increased "worry" at 2 to 8 weeks of age when they returned for the rescreen. Mothers who were more informed about hearing screening experienced decreased worry. Physicians who understand the screening process can support the family whose infant fails the screen, encourage the family to return for the rescreen, and follow-up with the family about the rescreen results. A second study[48] reported that mothers of infants with a false-positive screen did not report increased levels of stress or impact at 12 to 16 months or at 18 to 24 months. In addition, greater family resources were protective against persistent stress, whereas NICU stay contributed to prolonged stress.[48]

There is a continuum of increasing stress for families whose infants are identified with loss that increases as they progress though the hearing screen fail, rescreen fail, diagnostic fail, and intervention process.[24] Perception of stress at the time of diagnosis varies significantly among parents. Parents who are culturally deaf may have anticipated the diagnosis and be totally comfortable with it. Hearing parents of children diagnosed with a hearing loss perceive greater stress, which is, in part, related to the fear of disability.[1,4,24,47] About 95% of children with congenital hearing loss are born to hearing parents. Prompt sharing of diagnostic test results with the family and physician and referral to early intervention services by the audiologist on the day of diagnosis may facilitate the provision of needed information and support to parents to mediate stress.

If the physicians become aware of financial difficulties experienced by the family, the case manager from Part C Early Intervention should be alerted to assist the family to identify resources such as a hearing aid loaner program, Social Security benefit, Katie Beckett Program, or eligibility for Medicaid. The physician may also facilitate referrals to parent support groups such as Hands and Voices and Family Voices. Because half of the children identified with congenital hearing loss had been in an NICU, and about 40% of children with permanent hearing loss have other disabilities, these children may require the resources of a number of different medical and educational disciplines, adding to both the financial and emotional burden.[23,30]

In summary, infants born in 2010 with congenital hearing loss who have early identification, amplification, and intervention have enhanced opportunities for successful communication and academic achievement.

> — *Sir Charles Sherrington, 1940,*
> Man on His Nature, *p. 178*

About 13 million preterm deliveries occur per year around the world, with an overall incidence of about 9%.[67] In developed regions of the world, the incidence varies from 5% to 12%; it may be as high as 40% in less developed, poor areas.[24,48] Prematurity rates are steadily rising, especially in Western countries, with the advent of extensive infertility treatment and women's increased age at child bearing. For reasons of generational poverty and stress associated with discrimination, as well as lack of ready access to health care, the incidence stands at an all-time high of 18% for African-American families. Given significant advances in perinatology and neonatology in industrialized countries, survival rates have dramatically increased, even for infants with very low and extremely low birthweights. Today, more than 90% of infants born after 28 weeks' gestation. For infants born at 23 weeks, the probability of intact survival, that is, discharge home free of major disabilities, is less than 10%; it is less than 25% at 24 weeks and 35% at 25 weeks. Not until 26 weeks is the rate more than 50%.

Although infants born very early make up only a small percentage of births, they add disproportionately to the mortality, morbidity, and cost of medical care and of long-term disability services.[50,51,65] Preterm-born infants experience a range of adverse physical, behavioral, and mental health problems. Previously, it was believed that in the absence of major complications (e.g., large intraventricular hemorrhages, significant chronic lung disease, severe intrauterine growth restriction, necrotizing enterocolitis), preterm-born children would "catch up" over time. However, this is not the case. Recent research suggests that as preterm-born infants mature, they remain increasingly disadvantaged on many measures of cognitive function and mental processing. This is evidenced by problems related to academic achievement, behavior regulation, and social and emotional adaptation.[35,53,60] Prematurity is increasingly understood as a life-long condition.[16]

Not only to ensure survival, but also to foster best development of the increasing numbers of preterm infants, an understanding of their neurodevelopmental course is critical. This chapter provides a framework for the understanding and assessment of the preterm infant's neurobehavioral development as well as for the delivery of care from a neurodevelopmental perspective.

A NEURODEVELOPMENTAL FRAMEWORK

Preterm infants are fetuses who develop in extrauterine settings at a time when their brains are growing more rapidly than ever in their life span. They expect three securely inherited environments, namely their mother's womb, their parent's body, and their family and community's social group.[36] However, given medical and other complications, they are removed from the protective womb environment at this highly vulnerable phase of development. Prematurely born infants require care available only in the specialized, medical technological environments of newborn intensive care units (NICUs) and special care nurseries. Infants in these unexpected, yet medically necessary, environments are at high risk for organ impairments, the most devastating of which include chronic lung disease or bronchopulmonary dysplasia, intraventricular hemorrhage, retinopathy of prematurity, and necrotizing enterocolitis. Aside from such impairments, the mismatch of the fetal brain's expectation and the characteristics of the intensive or special care nursery provide significant challenges, which influence the infant's neurophysiologic, neuropsychological, psychoemotional, and psychosocial development. The fetus, and in turn the premature infant, expects total cutaneous-somesthetic input from amniotic fluid and kinesthetic input from the continuously reactive amniotic sac, which ensures mutual extensor-flexor modulation for head, trunk, and extremities. Fetal infants expect maternal diurnal rhythms to entrain differentiating states of consciousness and muted inputs to ready the primary senses of audition, olfaction, and gustation. Parental disruption of the expected emotional and physical preparation of pregnancy further adds to the challenge for preterm infants and parents. Even medically healthy preterm infants show an increase in later developmental difficulties, such as learning disabilities, lower intelligence quotients, executive function and attention deficit disorders, lower thresholds to fatigue, visual motor impairments, spatial processing disturbances, language comprehension and speech problems, emotional vulnerabilities, difficulties with self-regulation and self-esteem, and significant school performance deficits.[34] It appears that development in the extrauterine environment leads to different and potentially maladaptive developmental trajectories.

It is important to ask how to ensure these infants' smooth and balanced functioning outside of the womb. Realignment and emergence of the next developmental agenda best occur on the background of well-integrated functioning. This avoids reinforcement of costly maladaptive defense behaviors that all too readily spiral into vicious cycles of increasing distortion and disorganization, which in turn modify both brain structure and function.[6,8] It is not surprising that many of these infants later experience behavioral and neurologic difficulties. Understanding the neurodevelopmental expectations of the fetal infant provides a basis for modification of traditionally delivered newborn intensive care, which inadvertently increases stress and challenges the vulnerable preterm nervous system, and therewith the preterm child.

BRAIN-ENVIRONMENT INTERACTION

The environment influences the development of the fetal brain through the various senses of the infant, including the visual, auditory, cutaneous, tactile, somesthetic, kinesthetic, olfactory, and gustatory senses. Increasingly, animal and human studies indicate the importance of sensory information and experience in the womb for the complexity of fetal brain development. The sensory environment outside the womb presents stark contrasts and fully unexpected challenges to the fetal brain and may lead to malfunction and distortion of brain development and therewith neurobehavioral dysfunction. Human cortex begins development at about the sixth week of gestation, when the embryo is less than 1.5 cm in length, with the arrival of primitive corticipetal fibers, followed by the establishment of a superficial, primordial plexiform lamina. Cortical layer I, part of this plexiform lamina, appears to be necessary for the subsequent inside-out formation of the cortical plate, which represents the actual mammalian neocortical gray matter, and appears to play a significant role in the overall structural organization of the mammalian cerebral cortex. It controls the migration of all future neurons regardless of size, cortical location, or functional role.[49] Figure 43-1A presents these early

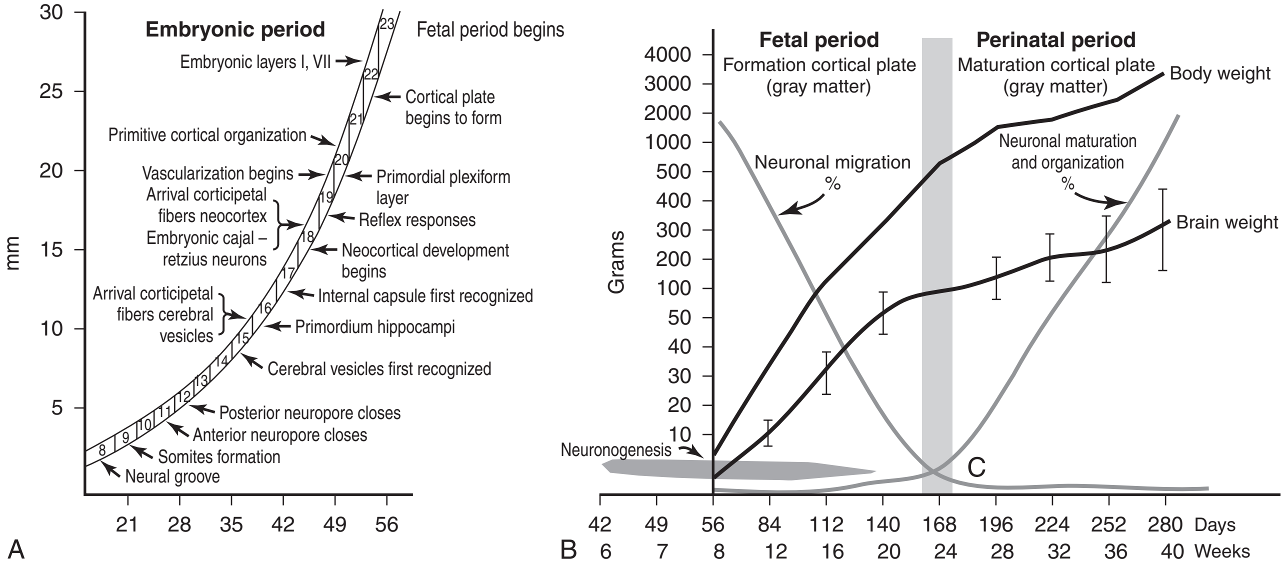

Figure 43–1. The major developmental events of the embryonic (A), fetal (B), and perinatal (C) periods of the prenatal ontogenesis of the human cerebral cortex. The embryonic period is characterized by the appearance of the cerebral vesicles, the arrival of the first corticipetal fibers, and the establishment of the primordial plexiform layer before the formation of the cortical plate. The fetal period is characterized by the process of neuronal migration and the inside-out formation of the cortical plate. The perinatal period is characterized by the ascending neuronal differentiation and maturation of the cortical plate (gray matter). (*Reprinted with permission from Marin-Padilla M: Pathogenesis of late-acquired leptomeningeal heterotopias and secondary cortical alterations: a Golgi study. In Galaburda AM, editor:* Dyslexia and development. *Cambridge, MA, 1993, Harvard University Press.)*

stages of cortical formation. By 6 weeks, the superficial musculature of the embryo is highly developed,[16] and cutaneous innervation and sensitivity are well on their way.[38] It begins with sensitivity in and about the mouth and extends to the nose and chin, eyelids, palms of the hands, genitalia, and the soles of the feet. Feedback loops are set up and dynamically construct the highly complex human central nervous system. Throughout development, a disproportionately large area of somatosensory cortex, dedicated to the earliest innervated surface regions, supports their specific evolutionary significance. It is these regions that appear difficult to satisfy and inhibit behaviorally in the fetal infant outside the womb.[1] Preterm infants brace with their feet, grasp with hands and feet, bring their hands to their mouths, search with mouth and tongue, suck, and make strong efforts to tuck themselves into flexion. This is especially apparent in the first 24 to 48 hours after delivery, before exhaustion leads to flaccidity.

Sixty years ago, Gesell and Armatruda[30] documented the organized specificity of very early fetal behavior. They showed specific turning away to a hair probe touch, whereas exploratory approach movements appeared to dominate in spontaneous undisturbed activity. This early appearance of the avoidance and approach continuum is in keeping with Denny-Brown's[26] model of motor system development, which involves gradual differentiation and integration of the dual antagonist extensor and flexor, that is, avoidance and approach movements. The differentiating spontaneous movement repertoire of the fetus is increasingly documented by ultrasound studies and indicates flexor-extensor adjustments; complex grasping and release sequences; interaction with the continuously available, pliable, and moving umbilical cord; exploration of face, neck, and head; sucking; holding on with one hand to the other; stepping; clasping one foot against the other; and so forth (Fig. 43-2). Such patterns set up increasingly complex feedback loops and generate the species—specifically complex human brain cytoarchitecture, with its enormously increased frontal-cortical systems.

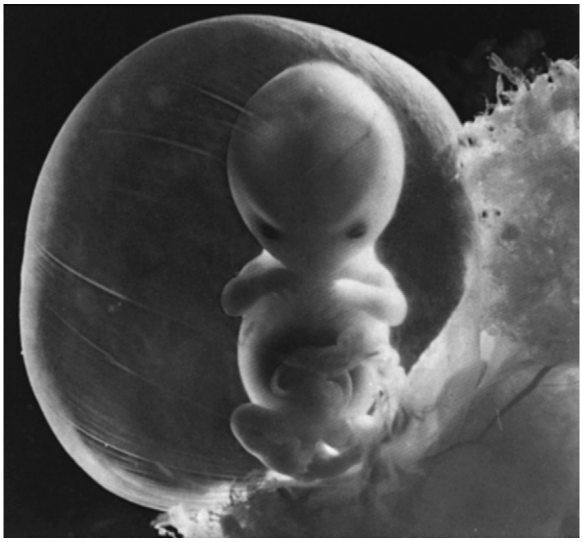

Figure 43–2. Seven weeks old, nearly an inch long, and weighing about 2 g: spontaneous exploratory behavior. *(Reproduced with permission from Als H, et al: Individualized behavioral and environmental care for the very low birth weight preterm infant at high risk for bronchopulmonary dysplasia: neonatal intensive care unit and developmental outcome,* Pediatrics *78:1123, 1986, Copyright © 1986 by the AAP.)*

Each of the millions of neurons in human cerebral cortex originates in the germinal lining of the ventricular system. In its prime, the germinal matrix releases as many as 100,000 cortical neurons per day, each of which migrates through the entire thickness of cortex to a specific location. These migrations occur in waves. They begin at about 8 postovulatory weeks and gradually tail off around 24 weeks of pregnancy, as Figure 43-1B shows, when neuronal maturation and organization increases dramatically, as Figure 43-1C indicates. Much of neuronal maturation and organization for the preterm infant occurs in the interaction with the extrauterine rather than the intrauterine environment. Each of the estimated 100 billion total human neurons, once migrated to their respective locations, develops dendritic and axonal interconnections with an average of 100 other cells. Although the first synaptic contacts are established as early as 7 weeks after conception, new cortical cells are generated at a low rate up until and beyond 40 weeks, and synapses continue to be established richly until age 5 years, more slowly, at least until age 18 years, and as now known, throughout the life span.[66] As cells become larger and more elaborately connected, more and more sulci and gyri develop, and different brain areas organize for different functions. A marked increase in the number of gyri occurs at the end of the second trimester and correlates with a concurrent growth spurt of the brain in terms of weight and a change in head contour from oval to prominent biparietal bossing. This is also the time when fetal behavior becomes increasingly complex with increased sucking on fingers or hand, grasping, extension and flexion rotations, increasingly discernible sleep and wake periods, and reactions to sound. Myelin, a fatty sheath somewhat like insulation, deposits around the axons and allows faster and highly repetitive conduction of impulses. It serves mainly to accommodate the increased length of the neuronal tracks with growth. Myelination occurs with peak activity around term birth and continues significantly until age 9 years and perceptibly into the 40s. Concurrent with the processes of cell differentiation, myelination, and neurobehavioral differentiation, neurochemical development occurs. Passage of impulses or messages between cells occurs by chemical neurotransmitters, which often are released only if up to four or five different regulatory systems co-occur in specific configurations. More than two dozen neurotransmitters have so far been identified, and no doubt there are many more. The sensitivities and densities of neurotransmitter receptors vary widely from brain region to region. Experience influences receptor development. Brain and sensory organs are interdependent for structural and functional development. The vulnerability of the support structure tissue adds to the picture of sensitivity and fragility of the preterm brain and the consequent sensitivity in overall functioning. Up to 50% of preterm infants born before 32 weeks' gestation have some degree of brain hemorrhage, and the incidence increases with the reduction in gestational age.[66]

Animal models have provided substantial evidence for the fine-tuned specificity of environmental inputs necessary for support of normal cortical ontogenesis in the course of sensitive periods of brain development and in the absence of focal lesions. The mechanisms implicated, when expected inputs are not forthcoming, are largely active inhibition of developing pathways consequent to overactivation of prematurely functional pathways, mediated by the endorphin system. Further support for a brain-based formulation of understanding preterm functioning comes from the Goldman-Rakiç[64a] research team, who showed that the specific connection systems developed in primates involve not only competition between axon terminals, and trophic feedback between presynaptic and postsynaptic cells, but also dynamic modification of connection at long distances due to functional activity. They concluded that changes in activity of distant yet synaptically related structures, which reduce or change specific input to cortex, affect subsequent developmental events, and provide the setting for new cell relations, the net outcome of which are unique cerebral cytoarchitectonic and chemoarchitectonic maps. Changes induced in mid-gestation in monkey thalamic fiber projections have yielded the formation of hybrid cortex, indicating that during rapid brain development, new cytoarchitectonic regions may arise by altered interactions, depending on unique combinations of intrinsic properties of the cortical neurons and afferent fibers involved.[66] Furthermore, differential cell death and other regressive events, which begin at about 24 weeks' gestation with the tailing off of cell migration, appear to be of key importance in sculpting developing cortex. These normally occurring regressive events are timed to be directly affected by the condition of premature birth. Of interest in this regard is also the function of subplate neurons, which are born in the generative zones and migrate to the primitive marginal zone before generation. The next step is migration of the neurons of the cortical plate themselves.[66] Subplate neurons provide a site for synaptic contact for axons that ascend from the thalamus and other cortical sites, termed *waiting* thalamocortical and corticocortical afferents, because their neuronal targets in the cortical plate have not yet arrived or differentiated. These subplate neurons establish a functional synaptic link between waiting afferents and their cortical targets. They guide ascending axons to their targets. When the subplate neurons are experimentally eliminated, thalamocortical afferents destined for overlying cortex fail to move superiorly into the cortex at the appropriate site and continue to grow aimlessly in the subcortical region.[66] Thus, subplate neurons are strongly involved in cerebral cortical organization. Furthermore, their descending axon collaterals guide the initial projections from cerebral cortex toward subcortical targets and toward other cortical sites. The subplate neuron layer in frontal human cortex reaches its peak at 32 to 34 weeks of gestation. This is a time that the preterm infant spends outside of the womb and experiences quite unexpected sensory inputs to primary cortical areas, such as visual cortex and somatosensory and auditory cortex. Visual cortex in the womb receives neither light, color, nor pattern input. The somatosensory and auditory cortex in the womb receives inputs, yet of a quite different kind from that outside the womb.

It seems warranted to hypothesize that messages transmitted from primary cortical regions to other cortical areas, including frontal cortex, are quite different for the preterm infant in the NICU than they would be for the fetus in the womb. It is also likely that waiting and regressive events are modified when the brain finds itself in unusual sensory circumstances, such as outside of the womb too early, and that cells are preserved, which might otherwise be eliminated, and cells are eliminated, which might otherwise be preserved. Monkeys delivered experimentally prematurely, while unchanged in visual cortical cell number, show significantly different visual cortical synapse formations in terms of size, type, and laminar distribution, compared with term monkeys tested at comparable post-term ages. The extent of difference correlates with the degree of prematurity.[20,21] Thus, although some events influence neuronal migration per se, other events, including difference in sensory input, appear to alter corticocortical connectivities and lead to unique cytoarchitectures and chemoarchitectures of cerebral cortex. This supports the finding that preterm infants show brain-based differences in neurofunctional performance. Premature activation of cortical pathways appears to inhibit later differentiations and interfere with appropriate development and sculpting, especially of cross-modal and frontal connection systems implicated in complex mental processing, as well as attention processes and self-regulation. Furthermore, corpus callosum differences have also been documented in preterm children studied at school age.[65]

In the term child, axonal and dendritic proliferation and the massive increase in outer layer cortical cell growth and differentiation lead to the enormous gyri and sulci formation of the human brain. This occurs in an environment of mother-mediated protection from environmental perturbations. It relies on a steady supply of nutrients, temperature control, and the presence of multiple regulating systems, including maternal-fetal chronobiologic and affective rhythms. The traditional NICU environment involves sensory overload and stands in stark mismatch to the developing nervous system's expectation.[14] Prolonged diffuse sleep states, unattended crying, supine positioning, routine and excessive handling, loud ambient sounds, lack of opportunity for sucking, and poorly timed social and caregiving interactions all exert deleterious effects on the immature brain and alter its subsequent development. How does one estimate the potential effects for the individual infant's nervous system moving too early from the relative equilibrium of the intrauterine aquatic econiche of the mother to the extrauterine terrestrial environment of the NICU?

A MODEL FOR OBSERVING THE PRETERM INFANT'S BEHAVIOR

According to Denny-Brown,[26] underlying the developing nervous system's striving for smoothness of integration is the tension between two basic antagonists of behavior, namely the exploratory and the avoiding response. The two dimensions are released simultaneously and stand in conflict with one another. If a threshold of organization-appropriate stimulation is passed, one may abruptly switch into the other. These two poles of behavior are basic to all functioning. This is demonstrated by the existence of somatosensory cortex single cells, which on stimulation produce toward or avoidance movements of the total body. The same principle operates in the gradual specialization of central arousal processes, which lead to functionally adaptive action patterns in altricial animals, such as suckling, nipple-grasping, huddling, and others. The principle of dual antagonist integration is helpful when assessing preterm infants' behavioral thresholds from integration to stress. In the well-integrated performance, the two antagonists of toward and avoidance modulate each other in bringing about an adaptive response. When an input is compelling to the fetal infant and matches interest and internal readiness, the infant will approach the input, react to and interact with it, seek it out, and become sensitized to it. When the input overloads the infant's neuronal network circuitry, the infant will defend against it, actively avoid the input, and withdraw from it. Both response patterns mutually modulate one another. For instance, the animate face of the interacting caregiver draws in the term newborn. As the infant's attention intensifies, eyes widen, eyebrows rise, mouth shapes toward the interacter, and fingers open and close softly. If the dampening processes of this intensity are poorly established, as in the preterm infant, the whole head may move forward; arms, legs, fingers, and toes extend toward the interacter; the mouth may shape forward; the wide-eyed gaze may trigger the visceral system; and the infant may hiccough or vomit. The response, which in the term infant is largely confined to face and hands, in the preterm infant may involve the entire body in an overly generalized way.

The overriding issue for preterm-born newborns is the integration of autonomic functions, such as respiration, heart rate, temperature control, digestion, and elimination, with the functioning of a motor system, which seeks to explore, contain itself, tuck into flexion, expand and extend, rotate, somersault, bring the hand to the mouth and suck, and grasp the umbilical cord. The motor system expects the cutaneous input of the amniotic fluid and amniotic sac wall, which support flexor-extensor balance. Preterm infant state organization no longer is supported by the maternal sleep-wake and rest-activity cycles, nor by the maternal hormonal, affective, and nutritional cycles. The model for observation and assessment of preterm infants' subsystem differentiation, termed *synactive*,[1] highlights the simultaneity of the subsystems in negotiation with one another and with the current environment. Systems continually open up and transform to new levels of more differentiated integration, from which the next steps of differentiation press to actualization.[1] To paraphrase Erikson (1962), self-actualization is participation with the world and interaction with another with a "minimum of defensive maneuvers and a maximum of activation; a minimum of idiosyncratic distortion and a maximum of joint validation."

BEHAVIORAL LANGUAGE OF THE PRETERM INFANT

Observation of preterm infants' behavior provides the base for estimation of the fetal infant brain's expectation for input, for inference of the infant's developmental goals for co-regulatory support, and for assessment of the infant's current functional competence. The formulation of observation and assessment is conceptually based in a combination of knowledge of fetal brain and behavior development, of term developmental functioning in negotiating the altered environment-fetus transaction, and of the individual-specific strategies employed by each infant. The behavior of the infant offers a common channel of expression of all three components and provides a base for inference of appropriate environment and care.[1]

Even fragile infants and those born very early display reliably observable behaviors in the form of autonomic and visceral responses, such as respiration patterns, color fluctuations, spitting, gagging, hiccoughing, and bowel movement strains. Infants also show observable movement patterns, postures, and tone of trunk, extremities, and face, exhibited in finger splays, arching, and grimacing, among others. Furthermore, the infants' levels of awareness, referred to as *states,* such as sleeping, wakefulness, and aroused upset, allow for valuable information. This makes possible an observation and assessment approach geared to documentation and understanding of such behaviors as evidence of stress and of competence and goal strivings. Such an approach provides the base for formal training and education in reading and assessment of the infant, with inference to reduce stress, support behavioral competence, and improve development.

The infant's vocabulary is identifiable along the lines of the three main systems outlined, the autonomic system, the motor system, and the state system, with special emphasis on the attention system. The infant's continued communication along these subsystem lines indicates whether what is currently going on around and within the infant is supportive of the infant's own goal strivings or is taxing, demanding, and potentially stressful for the infant.[1] Behavioral communications associated with each of the systems are delineated further in terms of various subchannels of communication within each system. Table 43-1 outlines the systems and their channels.

The autonomic system's efforts are observable in the infant's breathing patterns, color fluctuation, and visceral stability or instability. Simultaneously, the infant's motor system efforts are

TABLE 43–1 Channels of Communication

Autonomic System	Motor System	State System
Respiration pattern	Tone	Robustness of states
Color	Postural repertoire	Range of states
Visceral stability	Movements	Transition patterns

observable in the infant's maintenance of body tone as well as postural repertoire and movement patterns. State organization is observable in the infant's range of states available, the robustness and modulation of the available states, and the patterns of transition from state to state. To document an infant's ongoing communication, a methodology was developed for the recording of detailed observations of infants' naturalistically occurring behaviors in the NICU. The continuous time sampling method uses 2-minute time epochs as recording intervals. Figure 43-3 shows the behavior observation sheet, which is designed for use by trained observers at the infant's bed or care site. The infant is observed typically for about 20 minutes before a caregiver interacts with the infant, then throughout the duration of caregiving interaction, whether it is vital sign taking, suctioning, diaper change, or feeding, and then for at least 20 minutes after the caregiving interaction. Such an observation, especially if repeated over time, yields information regarding an infant's robustness and development as the infant attempts to integrate and make the best use of the care provided. The observations are used as the basis for

Figure 43–3. Behavior observation sheet. *(From Als H, et al: Individualized behavioral and environmental care for the very low birth weight preterm infant at high risk for bronchopulmonary dysplasia: neonatal intensive care unit and developmental outcome,* Pediatrics *78:1123, 1986.)*

caregiving suggestions and modifications in the adaptation of the environment's structure as well as the infant's individualized care plan.

As a rule, extension and diffuse behaviors are thought to reflect stress; flexion and well-modulated behaviors are thought to reflect self-regulatory competence. Regular respirations; pink color; smooth but not overly flexed active tone in arm, leg, and trunk position; smooth movements of arms, legs, and trunk; efforts and successes at tucking the trunk into flexion and bracing the legs all reflect self-regulatory competence. In the very young infant, hand-on-face behavior and mouthing may reflect stability; if overly frequent, however, this may indicate stress if not seizure activity. Suck-searching and sucking; hand clasp and foot clasp; hand-to-mouth efforts, grasping and holding on; face opening; frowning, ooh face, locking, cooing, and speech movements; heart rate between 120 and 160 beats per minute; breathing rate between 40 and 60 breaths per minute; and oxygen saturation (SaO_2) between 92% and 96% are typically read as effective self-regulation. *Stress and a low threshold to react* reflect great sensitivity. This is seen in irregular breathing, that is, slow or fast breathing and breathing pauses; color other than pink, that is, pale, webbed and mottled, red, dusky, grey or blue; tremors, startles, and twitches; visceral signs such as spit up, gags, hiccoughs, bowel movement grunts, passing gas, sounds, gasps, and sighs; flaccidity of arms, legs, and trunk; frequent extensor movement of arms and legs; stretch-drown behavior, frequent squirming, arching; frequent tongue extensions, gape face, and frequent grimacing; finger splays, airplane postures, salutes, sitting on air, and frequent fisting; fussing; frequent yawning, sneezing, and eye floating; frequent eye averting; heart rate less than 120 or greater than 160 beats per minute; respiratory rate of less than 40 or greater than 60 breaths per minute; and SaO_2 of less than 92% or higher than 96%.

The behavioral description of the infant's functioning in the course of an interaction observed and when anchored in the infant's current medical and family history provides the empirical basis from which to estimate the infant's current developmental goals. For instance, the infant may actively seek to pull himself or herself into flexion; seek to grasp and to tuck legs and feet into bedding and against the wall or surface of the incubator as if attempting to find boundaries and confinement; seek to bring hand and fingers to and into the mouth in order to suck; make efforts to breathe smoothly *with* rather than against the respirator, only to be interrupted repeatedly by the fixed respirator rate setting; attempt to settle back into sleep and restfulness after being care for, and thwarted repeatedly by ongoing sounds from alarms, faucets, voices, equipment being moved about, and so forth. On the basis of the goals inferred from the infant's behaviors observed, the next step is the exploration of supportive opportunities in terms of the environment and the delivery of care to enhance the infant's well-being and sense of competence and effectiveness, and therewith, development. Such considerations begin with appropriate support and nurturance of the infant's parents and family. Family members are understood as the primary co-regulators of the infant's development. They include an atmosphere and ambiance of care, nurturance, and respect for infant and family in the NICU environment; the organization and layout of the infant's care space; the structuring and delivery of specific medical and nursing care procedures and specialty care indicated; and an overall safeguarded and assured developmental perspective on care and environment provided. This is more fully described elsewhere.[2] Key points of the Newborn Individualized Developmental Care and Assessment Program (NIDCAP), are highlighted here.

Assurance of the parents' well-being as the infant's primary nurturers is important. The sensitization to the NICU environment in light of the family's key role is essential. Parents' attunement is exquisite in terms of the emotional ambiance of the setting, in which their immature infant lives and receives care. Parents find disturbing casual staff conversations; off-handed interactions; socializing of staff with one another; being talked over and about; conflict-ridden staff interactions, and so forth. All these activities indicate poor understanding of the parents' important role in the lives and care of their infants. Parents seek a respectful and supportive, professionally consistent environment, which instills a sense of trust through accountability and reliability. The infant's care space is often the infant's home for 3 or 4 months. Its organization and layout present a critical opportunity for support and nurturance of infant and family. Questions to ask include the following: Is the care area quiet, protected from traffic and activity not related to the infant's care? Is the infant's medical chart available to the family at all times? Is there individual and adjustable lighting for each infant's care area? Is there a telephone at each bedside for the family's outgoing calls? Is the family encouraged and guided to arrange, decorate, and personalize the care space, supportive of the infant's development and reflective of the family? Are there opportunities and furniture appropriate for the parents and siblings to be with the child at the bed space? Is staff knowledgeable and skilled in postpartum parent support, including care and comfort for the mother who breastfeeds her infant? Are there provisions for the family's opportunity for rooming with the infant in the NICU? Are there appropriate interpreter services available for all the languages presented by the parents in the NICU?

The infant's care involves many procedures, examinations, and therapeutic interventions delivered by staff from various disciplines. Structure and delivery of specific medical care procedures and specialty care as indicated must be carried out in a developmental perspective that permeates all care and environmental aspects. Primary care is of great importance in this model. It provides consistency of staffing, ensures continuity in care, and fosters intimate knowledge of infant and family. A primary care model effectively uses infants' communications as a basis for individualized care planning and care delivery. Parents are active members of the primary team and participate in rounds, care conferences, decision making, and care implementation. A developmental professional is important in supporting the specialty disciplines in maintaining a developmental perspective in all care planning and delivery. Figure 43-4 conceptualizes the developmental synactive model of care delivery, with focus on infant and family. The immediate safeguard of developmental structuring of care is the primary nursing team in collaboration with the primary physician, supported by specialists, such as respiratory, occupational, and physical therapists and social workers, among others, as indicated. A professional with a developmental specialty background and a nurse clinician

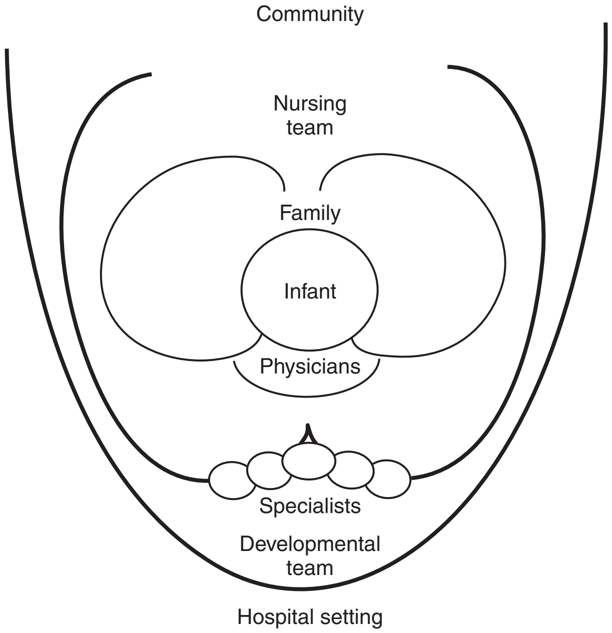

Figure 43–4. Developmental care model in the newborn intensive care unit. *(From Als H: Reading the preterm infant. In Goldson E, et al, editors:* Nurturing the premature infant: developmental interventions in the neonatal intensive care nursery. *New York, 1999, Oxford University Press, p 18.)*

form an effective team for provision of continued support for the caregivers' developmental perspective and collaboration. Qualifications for the developmental discipline professional include background and training in developmental and clinical pediatric or child psychology with specialization in NICU work in order to collaborate appropriately with the nurse clinician. Jointly they provide appropriate developmental support to the primary care teams in delivering supportive, individualized care in a developmental framework that encompasses infants and families.

TESTING THE VALIDITY OF NIDCAP

The NIDCAP Federation International is the professional organization that safeguards all NIDCAP training and professional certification in the NIDCAP approach to care.

The study of NIDCAP, which is based on reading the preterm infant's behavioral cues, is challenging. NIDCAP is theory driven and relationship based and requires systems integration. Its hardware and technology-free nature make adoption more difficult. The essence of developmental care lies in the continuous resourceful modification of care adapted to the individual infant's competence and vulnerabilities. It requires an open mind for "doing, learning, and coming to know."[31] Common misunderstandings of developmental care include minimal stimulation (fully covered incubators, protection from all visual and auditory contact, and clustered care of rapid routines at set intervals), and the developmental decoration approach to care (pretty nests and incubator covers; indirect lighting; whisper zones; yet routinized care as before). The change that developmental care requires is internal: a shift in mind and attitude, a "seeing anew." Further challenges exist for cultures and systems in which reflection and relationship-based processes are alien and in which medical professionals have ultimate authority for all decisions. Nurseries may differ in financial and leadership stability, staff relationships, patient census, staff-to-patient ratios, family characteristics, history, tradition and culture, organizational, communication and conflict resolution styles, and their distinctive competencies.[31] Yet the hopes and expectations of infants and families remain the same worldwide. Combining best technology and intensive care with the most sensitive, individualized, developmental care is a demanding responsibility. The NIDCAP training program (www.NIDCAP.org) focuses on education and training of multidisciplinary professional teams in NICUs. These in turn support, educate, and mentor all direct caregivers in the nursery in individualizing care and in fully integrating the parents.[45,70]

The several historical phase-lag trials that have studied NIDCAP are criticized for the possibility of contamination of the results by uncontrolled intervening variables. The preferred design is understandably that of randomized controlled trials. Trials of developmental interventions require large NICUs to provide simultaneous control and experimental group subjects. Staff must understand behavioral research. Cross-contamination of caregiver-implemented interventions is unavoidable; experimental effects must exceed contamination effects. Developmental care research requires experienced professionals, superb nursing and neonatology leadership, and extensive research expertise to safeguard the fidelity of the intervention implementation, the acquisition of complex databases, and the analysis of large data sets. Developmental research is highly labor intensive. Result generalizability is limited to study population and NICU characteristics.

Six randomized controlled trials[6,8,9,22,29,68] have investigated the effectiveness of developmental care. One incomplete and negative review[41] aside, results provided consistent evidence in infants 29 weeks' postmenstrual age and younger at birth, of improved lung function, feeding behavior, and growth, reduced length of hospitalization, and improved neurobehavioral and neurophysiologic functioning. A study of infants 28 to 32 weeks' postmenstrual age at birth[6] showed enhanced brain fiber tract development in frontal lobe and internal capsule. Figure 43-5 depicts the four electroencephalogram (EEG) coherence factor maps, which demonstrate for the intervention group increased coherence between left frontal regions and occipital and parietal regions (factors 7, 10, and 19), whereas midline central to occipital coherence was reduced (factor 11). Thus, developmental care intervention brought about changes in functional connectivity between brain regions, with preferential enhancement of frontal to occipital coherence (long distance coherences—newly emerging competencies) and pruning of central to occipital coherence (short distance coherence—already well-integrated competence). Moreover, Figure 43-6 shows the significantly enhanced white matter fiber tracts in an experimental group infant at 2 weeks' corrected age when compared with a control group infant from this study. The findings suggest more advanced white matter development in the frontal region and the internal capsule. In addition to the medical advantages for the infants born at 29 weeks' postmenstrual age or younger described earlier, a three-center trial[8] of such

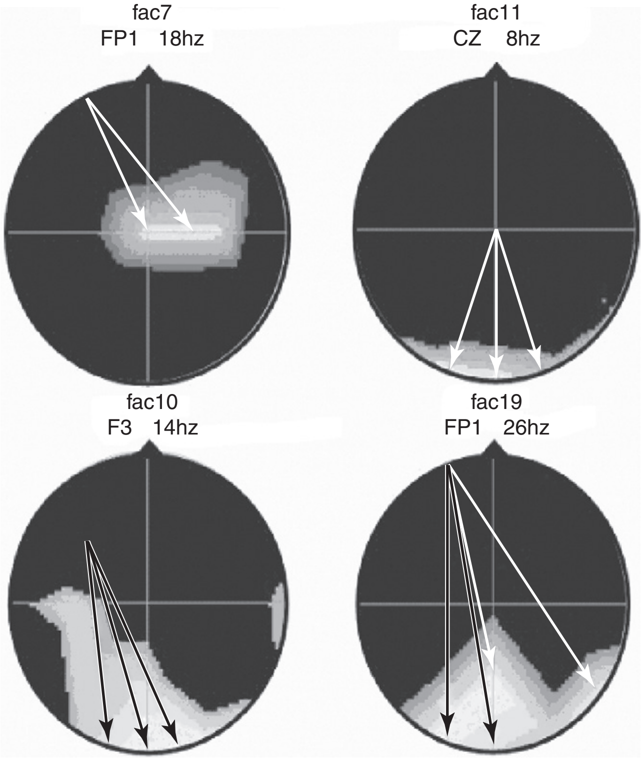

Figure 43–5. See color insert. Electroencephalographic coherence measures at 2 weeks' corrected age, control versus experimental group infants. Four heads, each corresponding to a utilized coherence factor, *top view, scalp left to image left*. Each shows the maximal loadings (correlations) of original coherence variables on the indicated factor. An index electrode and frequency are printed above each head. *Colored regions* indicate location, magnitude, and sign (*red,* positive; *blue,* negative) of maximally loading coherences on the factor. *Arrows* also illustrate coherence variables; however, *arrow color* compensates for signs of factor loadings on subsequent statistically derived canonical variates, thus illustrating how original coherence variables differ between experimental (*red,* increased; *green,* decreased) and control infants. *(From Als H, et al: Early experience alters brain function and structure,* Pediatrics *113:847, 2004. Copyright © 2004 by the AAP.)*

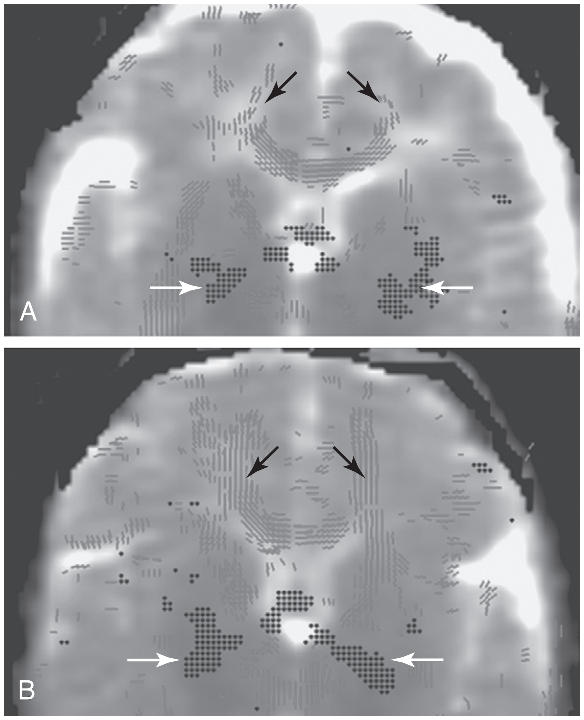

Figure 43–6. See color insert. Comparison of control and experimental group infants, at 2 weeks' corrected age, with magnetic resonance imaging and diffusion tensor imaging. Examples of diffusion tensor maps from identical axial slices through the frontal lobes of a representative control (**A**) and an experimental group (**B**) infant obtained at 2 weeks' corrected age. In each example, the principal eigenvectors (shown in *red* and *black*) overlie the apparent diffusion coefficient (ADC) map to show anisotropy in white matter. The *red lines* denote eigenvectors located within the plane of the image, and the *black dots* indicate eigenvectors oriented mostly perpendicular to the image plane. The ratio E1/E3 has been used as a threshold to show only eigenvectors at those voxels where E1/E3 exceeds a threshold value of 1.3 in both images. Note the greater anisotropy of white matter found in the experimental infant (**B**) compared with the control infant (**A**), at the posterior limbs of the internal capsule (*white arrows* in **A** and **B**) and the frontal white matter adjacent to the corpus callosum (*black arrows* in **A** and **B**). The greater anisotropy found in the experimental infant (**B**) suggests more advanced white matter development in these regions than is found in the control infant (**A**). *(Reproduced with permission from Als H, et al: Early experience alters brain function and structure,* Pediatrics *113:847, 2004. Copyright © 2004 by the AAP.)*

infants, from two transport and one inborn NICU, also showed positive results in infant and parent social emotional functioning, which included significantly lower parental stress, enhanced parental competence, and higher infant individualization.

Furthermore, recent research with fragile preterm infants (<1500 g) has demonstrated that even routine caregiving procedures that are performed frequently every day, such as diaper changes and breathing tube adjustments, are associated with major circulatory fluctuations, which increase the risk for brain injury.[47] Thus, research that demonstrates decreased pain scores, fewer hypoxic events, increased heart rate stability, and increased brain oxygenation during individualized nursing and caregiving events, such as individually adapted weighing and diaper changes,[23,64] become more important and provide invaluable evidence for the critical necessity of developmental care. Infants who received developmental care showed faster recoveries from procedures, and their parents reported an increase in their feelings of closeness with their preterm infant.[42]

The durability of NIDCAP effectiveness beyond the newborn period has been demonstrated in several studies. Infants who received NIDCAP in the NICU showed better Bayley mental and psychomotor developmental indexes at 3, 5,[56] and 9 months' corrected age,[9,10] as well as improved attention, interaction, cognitive planning, affect regulation, fine and gross motor modulation, and communication. A review of developmental care in the NICU for children born at less than 2000 g showed benefits that were sustained until 2 years of age.[17] At 3 years' corrected age, a Swedish study[43] documented better auditory processing and speech (Griffith Developmental Scales), fewer behavior symptoms, and better mother-child communication. At 6 years' corrected age,[69] the study showed higher survival rates without developmental disabilities.

Thus, developmental care is evidence based. It saves NICU and education system costs. NIDCAP training requires financial and staff time investment, yet is highly cost effective, given the documented care cost reductions of $4000 to $12,000 per developmental care infant. Because developmental care is in direct keeping with family-centered care, it promises to become the standard of care for future NICUs. The individualized approach requires continued NICU leadership support, aside from staff training, education, and role redefinition. All NICU work involves human interaction at many levels and in the complex interface of physical and emotional vulnerability. At its core is the tiny, immature, dependent, highly sensitive, and rapidly developing fetal infant and this infant's hopeful, open, and vulnerable parents. Infant and parents trust in, and count on, the caregiver's knowledge and skill and foremost the caregiver's sustained educated attention and emotional attunement and investment. Therein lay the challenge and the opportunity of developmental NICU care. Figures 43-7, 43-8,[3] and 43-9 show images of individualized developmental care in the NICU.

The results of developmental care are consistent with the underlying conceptual basis of the individualized brain-based developmental approach described, which views infants as active participants and structurers of their development, who seek continued regulatory support during initial stabilization and their developmental progression. Individualized care delivered by the infants' parents in collaboration with their professional care teams provides an extrauterine environment that supports overall infant and parent development. Preterm birth triggers the premature onset of sensitive periods. Preterm infants, who receive developmental care delivered in accordance with their own goals, show much reduced costs of such triggering and much improved functioning. This appears as a result of the individually attuned co-regulatory and continuous adaptation of the extrauterine sensory experiences in the nursery to the expectations of the rapidly developing brain.

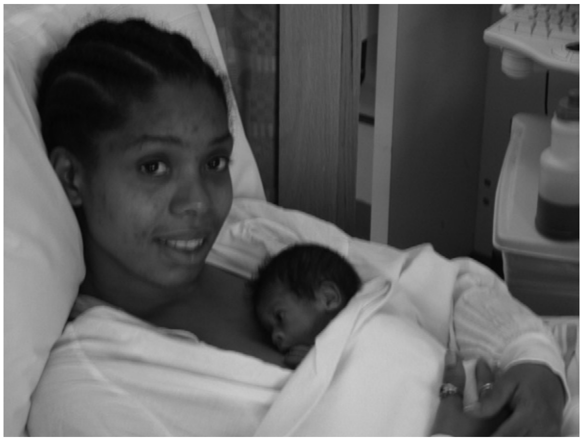

Figure 43–7. One week after birth, a 32-week preterm infant is held and cared for in skin-to-skin contact with her mother.

In summary, reading and trusting the preterm infant's behavior as meaningful communication moves traditional newborn intensive care delivery into a collaborative, relationship-based neurodevelopmental framework. It leads to respect for infants and families as mutually attuned to, and invested in, one another and as active structurers of their own development. It sees infants, parents, and professional caregivers engaged in continuous co-regulation with one another, and in turn in co-regulation with their physical and social environments. It highlights the importance of mutually supportive efforts to realize developmental and individual-specific expectations for the increased differentiation and modulation toward mutually shared goals. In turn, it improves outcome.

DIRECT ASSESSMENT OF PRETERM INFANTS' BEHAVIOR

Systematic, direct assessment of newborn functioning is more common in medical practice than is detailed naturalistic behavioral observation. Direct assessment of the newborn stems from two schools of thought, a more neurologically oriented mode of newborn assessment derived from the model of assessing adult neurologic status and a behaviorally, psychologically oriented mode of assessment derived primarily from psychological laboratory procedures for the study of specific newborn functions. These distinctions at times have led to confusion and artificial separation of aspects of newborn functioning, based largely on a misconception of separateness of neurologic and psychological functioning. More recently, there have been various efforts to combine the neurologic and behavioral aspects into more comprehensive assessments and to address the issues of preterm functioning. The goals of the neurologic assessment of the newborn typically are threefold: first, a diagnosis of a suspected neurologic problem; second, the evaluation of a known neurologic problem or pathologic process; third, the long-term prognosis for a newborn who recovers from a neurologic insult or who is judged at risk due to nonoptimal circumstances in pregnancy, labor, or delivery. The main focus for assessment of newborn neurologic functioning has been the assessment of a variety of reflexes. Peiper[57] was one of the first to describe extensively the reflex and behavioral repertoire of the newborn. His work provides a wealth of detailed information. McGraw[52] published studies specifically on newborn and infant neuromotor development. The French neurologic school under the leadership of André-Thomas and St.-Anne Dargassies brought out the first systematic neurologic examination of the newborn, translated into English in 1960.[62] It focuses on the normal infant's responses, and aside from a survey of the family history, pregnancy, delivery, birth conditions, and placenta, it includes an assessment of tone, reflexes (obligatory and more simple responses), and reactions (flexible and more complex responses). These clinicians for the first time presented a definite examination schedule in assessing the newborn. Prechtl and Beintema[59] developed the most popular examination published in English; Prechtl alone[58] published a second edition. The first part consists of observational assessment of resting posture, spontaneous motor activity, tremor, skin, respiratory rate, body temperature, body weight, skull (fontanelles, head circumference), face, and eyes. A second section includes sequential observation throughout the examination period, with state, postural, and movement assessment. In the Prechtl examination, the infant's state is continuously monitored and, if necessary, modified. For many of the elicited reflexes, the manual includes a statement about their clinical significance; for a number of them, their significance is unknown. The examination takes about 20 to 40 minutes, depending on how easily the infant is pacified. It involves some very taxing maneuvers, for example, three different types of Moro elicitations and the elicitation of the corneal reflex. Three parameters, the reactivity dimension (hyperexcitability or hypoexcitability), the stability dimension (easy or difficult to pacify), and the attention paid to asymmetry are of particular value in gaining a fuller understanding of the integrative intactness of the newborn. The examination systematizes the assessment of a diverse set of infant skills. Formal validity and reliability studies are not available. In the search for a simpler yet integrative assessment of functioning of the newborn's immediate postparturition status, Apgar[15] proposed a screening rating of 0 to 2 for five parameters, including heart rate, respiratory effort, reflex irritability, muscle tone, and color. This covers three aspects of autonomic system viability and two aspects of baseline intactness of the motor system. They are rated at 1, 5, and 10 minutes after delivery, often by the attending anesthesiologist or the obstetrician. Reliability training is not typically practiced. Nevertheless, the Apgar score shows considerable validity when extreme scores are examined. The probability of neonatal deaths is essentially nil with ratings of 8 or better and is very high with ratings of 0 to 3. There are no studies that assess the predictive significance of the change in Apgar scores from 1 to 5 to 10 minutes, although clinically, this appears the most often used index for immediate treatment and for relative confidence in the newborn's well-being. The use of the Apgar score for prediction in preterm infants is controversial. Nevertheless, used in context with other parameters of perinatal well-being, the Apgar score has held up across decades as a clinically valuable early descriptor. Organismic psychologists have long held that *observable behavior* is an expression of underlying neurologic status and brain function and that behavior may be used to identify specific brain lesions or diagnose more diffuse brain compromise. Such psychologists have widened the traditional medical perspective on the newborn to a broader developmental perspective. Approaches typically involve sampling from complex behaviors beyond the reflex repertoire.

Graham[32] developed the first behavioral assessment of the newborn with the goal of differentiating normal infants from brain-injured infants. The medical literature refers to her examination as a neurologic assessment, the psychological literature as a behavioral assessment. The examination includes pain threshold assessment to electric shock; motor responses including prone position, crawl, and defensive response; visual attention capacities such as object fixation and pursuit; and integrative parameters such as irritability and muscle tension. A standardization and validation study[33] identified reliable mean differences in a group of 30 normal term newborns compared with a group of 81 traumatized term newborns, with conditions of anoxia, mechanical trauma, infection, and medical disease. Nonetheless, predictive validity to ages 3 and 7 years was not encouraging. Rosenblith in 1961[59a] modified the Graham scale; she deleted the pain threshold test and divided the rest of the examination into two subscores, a motor score and a tactile adaptive score. Furthermore, she established two sensory scales, one to assess auditory responses and one to assess vision. She rated best rather than average performance in an effort to overcome behavioral instability in the newborn. Predictive validity studies showed low-level significance with 8-month Bayley measures. The Brazelton Neonatal Behavioral Assessment Scale[18,19,58] is a comprehensive behavioral assessment of the term newborn that incorporates and largely extends parameters assessed in the Graham-Rosenblith scales. It grew out of the collaboration of pediatrics (Brazelton) and psychology (Freedman) and was published as the Cambridge Newborn Behavioral and Neurological Scales. It was subsequently modified further in collaboration with psychologists Sameroff, Horowitz, Tronick, and Koslowski. Its main goal is the assessment of individuality in the spectrum of healthy term newborns. Therefore, in addition to assessing in a screening mode the basic reflex repertoire of the infant, it focuses on motor system integration, state regulation, and attention-interactive capacities, as well as reactivity, and on consoling capacities as measured in cuddliness, consolability, peak of excitement, rapidity of buildup to crying, and irritability. The adequacy of reflex performance is scored on four-point scales; the behavioral dimensions are rated on 26 nine-point behaviorally defined scales. Like the Graham-Rosenblith scales, the Brazelton Neonatal Behavioral Assessment Scale measures best performance. Extensive training is required to elicit the newborn's performance reliably and to score accurately the behavior observed. Training centers to achieve expertise in the use of the Brazelton scale have been established in Boston and other cities in the United States and in many countries around the world through the Brazelton Institute (Children's Hospital, Boston). Training is available to members of various medical, paramedical, psychological, and educational disciplines. Since publication, the Brazelton scale has received much attention and use in clinical and research areas. It provides an interactive approach and attends to more complex organizational parameters of functioning than do most other newborn assessments. The later editions have added supplemental items, which further qualify the behavior of the newborn. These are derived from the Neonatal Behavioral Assessment with Kansas supplements (1978)[37] and the Assessment of Preterm Infants' Behavior.[11]

The Brazelton Neonatal Behavioral Assessment Scale is distinguished from other newborn assessments in its use as an intervention with parents and medical staff. Employed in this manner, it is intended to improve and enhance the caregiver's attitude to and interaction with the infant. The intervention efforts with parents have involved low-risk and high-risk situations as well as term and preterm infants. Nugent and Brazeton give a clinical description of the use the scale in this manner.[55] The success of this work may well be related to the fact that the Brazelton assessment focuses on interactive and highly individualized parameters of newborn functioning. This focus enhances the caregiver's perception of the newborn as a competent, autonomous being. The use of the scale exerts a major impact on pediatric care delivery. Research use is extensive.

Scanlon and colleagues attempted to answer the need for a brief and easily administered neurobehavioral examination of the newborn for the study of obstetric medication effects. The resultant Early Neonatal Neurobehavioral Scale (ENNS)[61] combines several items from the Brazelton scale[18] and the neurologic examination of Prechtl and Beintema.[59] The testing sequence is designed to arouse the infant to maximal activation during the course of the examination. Tests involve physical manipulation and disturbing, aversive stimuli, such as measures of muscle tone or pinprick. These are performed before the measures of integrative neurologic function. The central theme of the ENNS is the assessment of response decrement with repeated elicitation, which is seen as an index of cortical functioning as distinct from subcortical motor functions supposedly traditionally assessed in neurologic examinations of the newborn. Furthermore, Scanlon and coworkers consider response decrement as independent of state arousal. The sequence of ENNS items moves from repeated pinpricks (12) to pull-to-sit, arm recoil, assessment of trunk tone, general body tone, rooting response, sucking, response to repeated Moro maneuvers (12), placing response, and the general observation of alertness, followed by an overall rating of the newborn's functioning. The ENNS takes between 5 and 7 minutes to administer and requires training, yet background in neurology or psychology is not required. It is a repetitive, rapid, and partial screen of central nervous system integrity.

The Amiel-Tison assessment,[13] the Neurologic and Adaptive Capacity Score, based on the French school led by St.-Anne Dargassies and Minkowski, is geared to the detection and differentiation of drug depression from perinatal asphyxia and birth trauma and, furthermore, to the prediction of later outcome. In Amiel-Tison's view, subtle imbalances of extensor and flexor tone of the neck muscles and the upper extremities are related to perinatal asphyxia or mild birth trauma, whereas general mild hypotonia, mediocre primary reflex responses, and absent or poor habituation to repeated stimuli are more frequently related to drug depression. Amiel-Tison incorporates items from Scanlon's ENNS and from the Brazelton scale and contends that both tests have shortcomings. She considers the Brazelton too complicated and time consuming and the ENNS too noxious and lacking the assessment of motor tone, which Amiel-Tison considers diagnostic. Her examination yields a single total score, a feature desired by many clinicians. The differentiating and predictive value of the Neurologic and Adaptive Capacity Score remains to be determined. Attention to active tone is clearly important. The speed and selectiveness of the items, together with the global nature of scoring (0, 1, 2), does not recommend the assessment for the evaluation of subtle neurointegrative differences, restricting its use to relatively vigorous term infants.

OVERVIEW OF PRETERM NEWBORN NEUROBEHAVIORAL ASSESSMENTS

Several tests have been developed specifically for the assessment of preterm functioning. The Albert Einstein Neonatal Neurobehavioral Assessment Scale[25] has as its goal a parsimonious, reliable, yet comprehensive evaluation of neurologic and behavioral organization of both the preterm and full term newborn. The 30- to 45-minute examination assesses performance on 20 specific behavioral test items and yields additional ratings on four summary scales. Like the Brazelton scale, the test pays attention to the state of the infant. Administration directions are identical to those of the

Brazelton scale. Of the 20 specific behavioral items, 13 are directly derived from the Brazelton scale, 4 are drawn from Prechtl's examination, and 1 is derived from the Dubowitz Assessment of Gestational Age[27] and is described in Amiel-Tison's examination described previously. All scales are four-point scales. Despite the instruction to work for optimal performance, the administration directions per item are highly specific and preclude optimal performance. High-risk preterm infants assessed approximately at term-equivalent age did significantly more poorly than term infants on all orientation items, a number of the reflex items tested, active mobility, passive tone, and the summary items of state profile and latency to consolation. When low-risk preterm and healthy infants were compared at term, there was greater similarity than dissimilarity between the two groups. Comparison of high-risk term and preterm infants with low-risk term and preterm groups with the Einstein scale showed that term asphyxiated newborns and those who were small for gestational age had the most abnormal responses. Predictive validity of the Einstein scale has been shown to improve from 1 to 3 years of age.

The Dubowitz Neurological Assessment of the Preterm and Fullterm Newborn Infant draws primarily from the earlier assessment of gestational age,[27] supplemented by Prechtl and Beintema items,[59] items from St.-Anne Dargassies[63] and items from the Brazelton Neonatal Behavioral Assessment Scale.[18] This compilation of items was pretested with a newborn population of about 500 infants, including preterm and term. A chart with four- to five-point range descriptors and stick-figure newborn drawings facilitates scoring of some 32 items of newborn functioning. According to the authors, the examination does not require particular experience or expertise in neonatal neurology. Performance time is 10 to 15 minutes. A cautionary note is indicated regarding use of this stressful examination for infants born with very low birthweight and very early.

This caution also applies to the Neurobehavioral Assessment of the Preterm Infant.[44] Few assessments have undergone as thorough a design and item evaluation process as this assessment. Korner and associates detail the process of item development, reliability, and validity. The test's goal is to document weekly change in neurobehavioral functioning from 32 weeks to term age. Test items include motor development, vigor, scarf sign, popliteal angle, alertness and orientation, percent asleep ratings, irritability, and vigor of crying. Despite rigorous test development, the testing items lack a unifying theoretical construct and have not shown predictive validity or reliability in differentiation of subgroups or intervention effects.

The most recent combination of neurological, maturational, and behavioral items is the Neonatal Intensive Care Unit Network Neurobehavioral Scale.[46] This scale assesses and scores the full range of infant neurobehavioral performance. It assesses infant stress, abstinence and withdrawal behaviors, neurologic functioning, and features of gestational age assessment. It attempts to provide a comprehensive evaluation of the neurobehavioral performance of the high-risk and substance-exposed infant during the perinatal period. Its use is applicable for a great variety of infants of varying histories and gestational ages, as long as the infants are stable. The Neonatal Intensive Care Unit Network Neurobehavioral Scale follows a standardized administration format that removes the examiner from the behavior assessed. The order of items is strictly specified. If the infant is in the wrong state for an item, the item is skipped. There are, furthermore, specific guidelines for when and how to console the infant. The test provides an estimate of how an infant at a particular time responds to a standardized set and sequence of events. This shortens the examination's administration. Training required is brief and quite simple. There is little need for judgment. Skill to elicit best performance is not required. As such, the Neonatal Intensive Care Unit Network Neurobehavioral Scale resembles more the Neurobehavioral Assessment of the Preterm Infant than the Brazelton scale. It lacks a theoretical conceptual framework, and is purposely not a relationship-based interactive assessment. This makes it questionable for the fair assessment of the newborn infant, who is neuroessentially social.

A detailed review of several of the previously referenced newborn assessments appears in a special edition of the journal *Mental Retardation and Developmental Disabilities Research Reviews*.[5]

THE ASSESSMENT OF PRETERM INFANTS' BEHAVIOR

The specificity and organization of preterm and full-term infants' behavioral functioning is assessed most comprehensively in the Assessment of Preterm Infants' Behavior (APIB). The APIB is designed to observe the infant's threshold to disorganization, functional stability, and ability to recover from disorganization as measured in degree of differentiation and modulation of the balanced subsystems.[5,11,12] The main objective of the APIB is the assessment of infant individuality and competence, based on observation of the behavioral subsystems in interaction with each other and with the environment. The goal is to determine the infant's reactivity and thresholds from modulation to disorganization in the face of varied environmental challenges.

The test items of the Brazelton scale[18] are organized into six increasingly vigorous packages of questions posed to the infant. Each package presents the infant with increasingly challenging, complex interactions and quantifies the infant's behavioral organizational response patterns. Stimuli presented in the initial packages are distal in nature. For example, while the infant is sleeping, the response to repeated light from a flashlight or to the repeated sound of a rattle is noted. As the examination progresses, the stimuli become proximal in nature and involve cutaneous tactile, kinesthetic, and vestibular inputs. For example, responses to cutaneous input to the face are noted as well as responses to movement of the limbs and trunk, as elicited for instance in the pull-to-sit or stepping maneuvers. The sixth package engages the infant to attend to, localize, or visually track a variety of animate and inanimate sounds and sights related to objects and the examiner's face and voice. The organization of the autonomic, motor, state and self-regulatory subsystems are scored on nine-point rating scales before, during, and after each of the six packages. Because package six requires focused alertness, the attention-interaction subsystem is additionally scored before, during, and after this package. A measure of the amount of examiner facilitation is included for each package to assess the amount of examiner-supplied environmental support necessary to help the infant maintain or regain subsystem integration while responding to the questions of the examination.

The APIB scores reflect the infant's organization of the five subsystems in the course of the interactive assessment and the amount of examiner facilitation required; together, they are referred to as *system scores*. These system scores represent an innovative component of newborn assessment. They focus on the simultaneity of subsystems in their interplay and in turn their respective interplay with the environment, as based in the synactive theory of development.[18] For the traditional newborn examiner, this component of the APIB is the most challenging because it requires a dynamic perspective of neurodevelopment, human evolution, and self-constructing neurologic and pediatric thinking and education. Training in the assessment encompasses background teaching in neurodevelopment and human evolution.

In addition to the system scores, each of the responses elicited in the course of the APIB dialogue with the infant is assessed along various dimensions. Overall, the APIB yields 285 raw scores, which are reduced to 32 a priori summary scores. Most of the APIB raw scores are scored on one- to nine-point scales, with 1 representing well-organized behavior and 9 representing poorly organized behavior. The remaining APIB raw scores are scored on zero- to three-point scales, in which a score of 0 reflects absence of a response, and a score of 3 an obligatory, hyperreactive response.

APIB summary scores are obtained by averaging specified APIB raw scores. For the subgroup of APIB raw scores referred to as system scores, each system summary score remains scaled from one to nine, in which 1 represents well-organized behavior and 9 represents poorly organized behavior. The remaining nine-point APIB raw scores are converted to summary scores with reversed scale direction, in which 1 represents disorganized behavior and 9 represents well-organized behavior. The APIB raw scores, which use zero- to three-point scaling, yield summary scores on a similar zero- to three-point scale, in which 0 indicates that a response was not obtained and 3 indicates an obligatory, hyperreactive, or too frequently observed response.

The APIB requires extensive training by a certified APIB trainer. Ninety percent inter-rater reliability is the established minimal criterion for use of the APIB. APIB test-retest reliability across 4 weeks (40 to 44 weeks) for system scores and cluster-analyzed profile groups is highly stable.[7]

For psychological tests, four categories of validity are required: predictive, concurrent, content, and construct validity. APIB predictive validity has been established with a behavioral assessment known as the Kangaroo Box Paradigm and the Bayley Scales of Infant Development, based on a sample of 160 healthy preterm and term infants restudied at 9 months.[10] A second study reports predictive validity to neuropsychological testing at 5 years of age as well as to the Kangaroo Box Paradigm at 5 years of age.[7] Concurrent validity has been established in a study comparing APIB scores and quantified EEG with topographic mapping performed at the same age point. Similarly, unrestricted spectral coherence of brain electrical activity was highly correlated with APIB behavioral factor scores in a study of 312 newborn infants with varying gestational ages. All infants were examined 2 weeks after expected term due date.[28] Brain structural assessment with magnetic resonance imaging,[39,40] as well as with magnetic resonance diffusion tensor imaging,[6,39] also showed significant correlation to APIB behavioral scores. All studies implicated frontal lobe parameters as associated with attention system scores and overall APIB system modulation. This points to a differential vulnerability of frontal systems in the early-born preterm population. Content validity refers to the degree that test items sample what the test purports to measure. This is important in order to allow valid inferences from test results. APIB subsystem scales operationalize the behavioral constructs measured by the APIB. Whether the specific behavioral items selected as indicative of subsystem function truly sample subsystem function must be addressed in future studies of the APIB's relationship to other measures of the same construct. Such measures are not available at this time. Related to content validity is construct validity. There are several ways to establish construct validity. One way is by comparison of test scores for groups of subjects that are known to differ, or by comparison of subjects that are theorized to perform differently. The APIB distinguishes well between groups of infants that differ on various dimensions. These include differences in gestational age and in degree of illness.[28] Another method of assessing construct validity occurs when the theory suggests how an intervention should alter behavior relevant to the construct. All intervention studies reported to date and based in the synactive theory of development have demonstrated that intervention group infants, compared with control group infants, showed significantly improved functioning as measured with the APIB. This supports high construct validity. Overall, it appears that the APIB has good test properties, especially compared with some of the other newborn assessments reviewed previously.[6-10,54]

The past four decades thus have seen much work devoted to the development of assessments that capture the neurobehavioral repertoire of the preterm infant. Earlier assessments were often compilations of reflex behaviors and ignored organizational capacities and competencies. Although the work of Graham and Rosenblith set the stage for later neurobehavioral assessment, Brazelton was the first to emphasize the individual competencies of the term newborn. The APIB has taken neurobehavioral assessment a step further by articulation of the behavioral organization constructs of differentiation and modulation of functioning. The APIB is based in comprehensive developmental theory, which makes APIB results cohesive and interpretable in a neurodevelopmental dynamic framework.

The implications of the preterm assessments presented, especially those of the APIB, suggest that even when the physical health of the preterm infant is ensured, premature birth itself appears to contribute to behavioral and electrophysiologic differences in functioning. Preterm infants emerge as more sensitive and easily disorganized and have much greater difficulty with self-regulation. Their motor systems show poor modulation, and their autonomic reactivity is more costly. Their brain function, especially of association cortical and, in particular, frontal lobe regions, reflects these differences. The differences appear to hold up across time into school age. Poorer state and attention scores are more typical of preterm infants than healthy term infants.

They are more difficult to bring to alertness; they are more likely to move from sleep states into uncontrolled crying; and they show more stress with state transition. They muster often only strained alertness, diffuse protest, and diffuse sleep. They require more facilitation for state maintenance and self-regulation. They are likely to exhibit attention difficulties and distractibility in later infancy and school age, even in the face of normal intelligence. The attention measures show the strongest correlations with EEG coherence factor.[28] Clinical experience with older children indicates that difficulties in concentration and problems with attention are frequent in former preterm children, even those spared significant medical sequelae. Attention regulation problems are also the most common subtle neurologic residua after recovery from even very mild encephalopathy. Similarly, mild reduction of clinical EEG background voltages is a subtle residuum of anoxic encephalopathy, toxic, or metabolic derangement. Thus, the finding of significant reduction of EEG spectral content as the legacy of prematurity takes on added significance.

The prominent frontal region involvement, as identified by EEG spectral coherence measures, and found in even healthy preterm infants, is of interest given the known association of attention disorders with frontal dysfunction. The frontal lobe may be relatively more sensitive to subtle insult than other regions. Thus, the simple fact of premature extrauterine experience may have important consequences. The extrauterine multisensory experience before term may trigger sensitive periods at a time when the infant is not in a position to incorporate appropriately such sensory influences, thereby inducing altered subsequent neural development. Follow-up at 8 years corrected age appears to indicate that the earliest born preterm infants exhibit extraordinary variability of cognitive processing. Figure 43-10 shows the example of an early born, medically healthy child's performance profile on a number of the neuropsychological subtests.[4,70] Although this child shows both a verbal and performance intelligence quotient both of 115 (i.e., a standard deviation above the mean for age), this child had great difficulty in the second-grade classroom. The child's subtest profile indicates extraordinarily high performance on several subtests; for example, Similarities (Wechsler Intelligence Scale for Children, Revised) and Gestalt Closure (Kaufman Assessment Battery for Children) are 3 standard deviations above the mean, which is in the very superior or gifted range, whereas other subtests show performance at or below a standard deviation below the mean for age, in the dull normal to borderline range. These include Arithmetic (Wechsler Intelligence Scale for Children, Revised), Matrix Analogies (Kaufman Assessment Battery for Children), and the Rey-Osterreith Complex Figure Test-Recall condition. Subdomain discrepancy with valleys of disability is typical for children with brain lesions. Yet, such children do not show the extraordinary peaks of excellence seen in presumably focally brain-intact, yet very early born, preterm infants. This performance picture appears to indicate brain reorganization rather than lesion, owing to very early difference in brain-environment interaction. This difference appears to accentuate differentially the development of certain brain systems, which are ready to take advantage of the extrauterine challenge, whereas it inhibits other brain systems, which expect intrauterine inputs for several more months.

SUMMARY

Intrauterine and extrauterine environments appear to influence brain development differentially. Provision of co-regulatory, neurodevelopmental support and care for the preterm infant understood as biologically evolved in a neuroregulatory family system may enhance neurobehavioral, neuroelectrophysiologic, and family functioning not only for high-risk but also for medically low-risk preterm infants.

During the perinatal period from 24 weeks' gestation to the time of term birth, the human cortex appears particularly vulnerable because its neurons are undergoing significant structural and functional transformations in response to

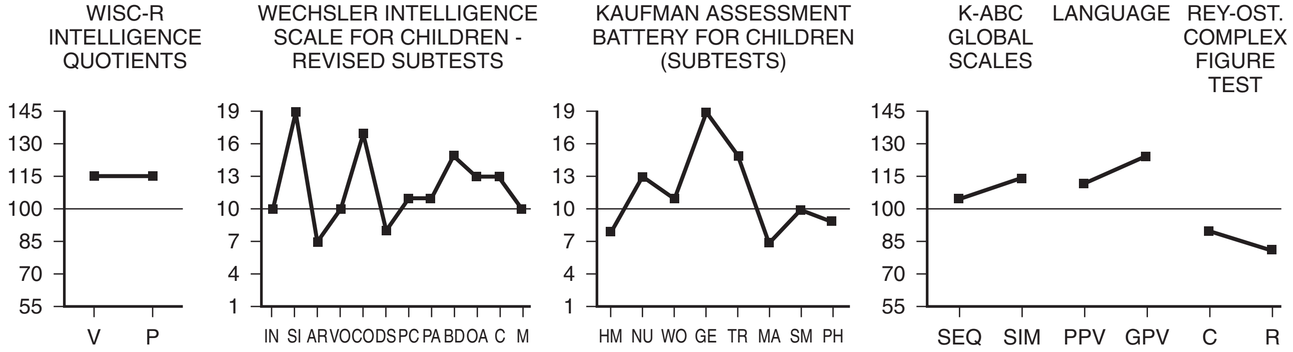

Figure 43–10. Test profile of early-born, medically healthy preterm child. Wechsler Intelligence Scale for Children, Revised (WISC-R) Intelligence Quotients: P, performance IQ; V, verbal IQ. WISC-R Subtests: AR, arithmetic; BD, block design; CO, coding; DS, digit span; IN, information; M, mazes; OA, object assembly; PA, picture arrangement; PC, picture completion; SI, similarities; VO, vocabulary. Kaufman Assessment Battery for Children (K-ABC) Subtests: GE, gestalt closure; HM, hand movements; MA, matrix analogies; NU, number recall; PH, photo series; SM, similarities; TR, triangles; WO, work order. K-ABC Global Scales: SEQ, sequential processing; SIM, simultaneous processing. incoming fibers. To achieve its complex organization, the cerebral cortex must be subject to significant developmental constraints. Disruptions through injury or violation in evolved expectancy of input may well result in disturbance of the cortex's anatomic and neurochemical integrity and therewith challenge the normal developmental constraints of the still-growing cortex. Thus, the neurofunctional differences observed in preterm infants may represent secondary modifications and readaptations to locally disturbed cortical developments. The differential vulnerability of the frontal lobe system is of particular importance in designing preventive and ameliorative brain-nurturing environments and care provision. The frontal lobe is the human's most species-specific lobe of the brain, evolved most recently, is most complexly organized, and is critically important for complex planning and communication. The frontal lobe is necessary to foresee and predict outcome without trial-and-error action sequences. It inhibits impulsive stimulus reactions and supports reflective analysis of complex, multidimensional, open-ended situations. It supports delay of gratification and suspension of judgment and action, whereas it affords sustained inquiry in the face of ambiguity and uncertainty. It diffuses pressure toward solutions but maintains initiative and goal orientation. In addition, it supports decision power and prioritization. This uniquely human species survival organ of the cortex appears to be simultaneously the most easily damaged or altered. In the "good-enough" term situation, it appears to be nurtured in the social-emotional communicative matrix of good-enough parenting in good-enough social groups. In unexpected situations, such as in preterm circumstances, it requires special attention for preventive and ameliorative care.

Social contexts have evolved in the course of human phylogeny, are specific and fine-tuned, and provide good-enough environments for the human cortex to unfold, initially in the womb, then outside the womb. They ensure the continuation of human evolution. With the advances in medical technology, even very immature nervous systems survive and develop outside the womb. However, the social contexts of traditional special care nurseries often bring with them less than adequate support for immature nervous systems, leading to maladaptations and disabilities, yet also perhaps to accelerations and extraordinary abilities. Detailed observation of the behavior of the fetus who is displaced from the uterus into the NICU provides the opportunities to estimate and infer appropriate environmental and social contexts, sufficiently astute to support the highly sensitive and vulnerable nervous systems of preterm infants in their developmental progressions.

The information presented here indicates that an individualized, behavioral-developmental approach to care improves outcome not only medically but also behaviorally, neurophysiologically, and in terms of brain structure. Such an approach emphasizes from early on the infant's own strengths and apparent developmental goals and institutes support for self-regulatory competence and achievement of these goals. The results indicate that increase in support to behavioral self-regulation improves developmental outcome, perhaps by prevention of active inhibition of central nervous system pathways due to inappropriate inputs during a highly sensitive period of brain development. Developmentally appropriate care is associated with improved cortical and specifically frontal lobe development. Adaptations of environment and care are productive when based on the astute observation and direct assessment of individual infants' current behavior and on the interpretation of behavior in a framework of regulatory efforts toward self-set goals of continued differentiation and self-construction. The results support the formulation of highly specific brain expectations during early development, and neurodevelopmental care emerges as neonatology's new frontier.

CHAPTER 44

The Respiratory System

PART 1

Lung Development and Maturation

Alan H. Jobe

A BRIEF HISTORY

An understanding of lung development and maturation is central to the care of preterm infants because lung function is so critical to survival of the preterm. Although von Neergaard reported the presence of air-fluid interfaces in lungs in 1929, there was no substantial increase in the understanding of lung immaturity until Pattle and Clements noted the presence of surfactant in pulmonary edema foam and lung extracts. Avery and Mead in 1959 correlated respiratory failure with decreased surfactant levels in saline extracts from the lungs of infants with respiratory distress syndrome (RDS).[2] Once the association between atelectasis with hyaline membranes and surfactant levels was appreciated, a large international research effort focused on the surfactant system. The first direct clinical benefit was identified in 1971 when the lecithin-sphingomyelin (L-S) ratio using amniotic fluid was used to predict lung immaturity and the risk for RDS in preterm infants.[16] The usefulness of phosphatidylglycerol measurements for lung maturity testing was appreciated by 1976.[18] The development of continuous positive airway pressure to maintain functional residual capacity (FRC) for infants with RDS was the initial progress with respiratory support. Liggins and Howie first reported a decreased incidence in RDS with maternal corticosteroid treatments in 1972.[34] The feasibility of surfactant treatment for lung immaturity was demonstrated in animal models in the 1970s, primarily by Enhörning and Robertson, and surfactant was successfully used in humans by Fujiwara and colleagues in 1980. This research resulted in the development of perhaps the two most effective treatments in neonatology—antenatal corticosteroids and postnatal surfactant for RDS. This progress in the application of research to the pulmonary care of the infant will no doubt continue as molecular and cell biologic observations improve the general understanding of lung development.[49] A major interest for the future is the prevention of chronic lung disease (CLD) in infants who are very preterm.

LUNG STRUCTURAL DEVELOPMENT

Embryonic Period

The lung first appears as a ventral bud off the esophagus just caudal to the laryngotracheal sulcus.[10] The grooves between the lung bud and the esophagus deepen, and the bud elongates within the surrounding mesenchyme and divides to form the main stem bronchi (Fig. 44-1). Subsequent dichotomous branching gives rise to the conducting airways. The branching of the endodermal endothelium is controlled by the underlying mesenchyme because removal of the mesenchyme stops branching. Transplantation of the mesenchyme from a branching airway to more proximal airway structures induces budding in the new location.

The commitment of endodermal cells to epithelial cell lineages requires the expression of families of transcription factors that include thyroid transcription factor-1, forkhead gene family members, and others.[48] At least 15 homeobox domain-containing genes (*HOX* genes) also contribute to lung morphogenesis. Multiple other growth and differentiation factors, such as retinoic acid and the fibroblast growth factor family members (FGF)-7 and FGF-10 and their receptors are temporally and spatially expressed and are critical to early lung morphogenesis and subsequent development. Genetic ablation of these transcription and growth factors, among others, causes lung developmental abnormalities that range from tracheoesophageal fistula and altered branching morphogenesis to severe lung hypoplasia and complete aplasia of the lungs. Lobar airways are formed by about 37 days, with progression to segmental airways by 42 days and subsegmental bronchi by 48 days in the human fetus. The pulmonary vasculature branches off the sixth aortic arch to form a vascular plexus in the mesenchyme of the lung bud. Major regulators of vascular development are vascular endothelial growth factor and its receptors in the mesenchyme. Vascular development additionally requires extracellular matrix (fibronectin, laminin, type IV collagen) and other growth factors such as platelet-derived growth factor. The pulmonary artery can be identified by about 37 days, and venous structures appear somewhat later. Abnormalities in early lung embryogenesis cause tracheoesophageal syndromes, branching morphogenesis abnormalities, and aplasia.

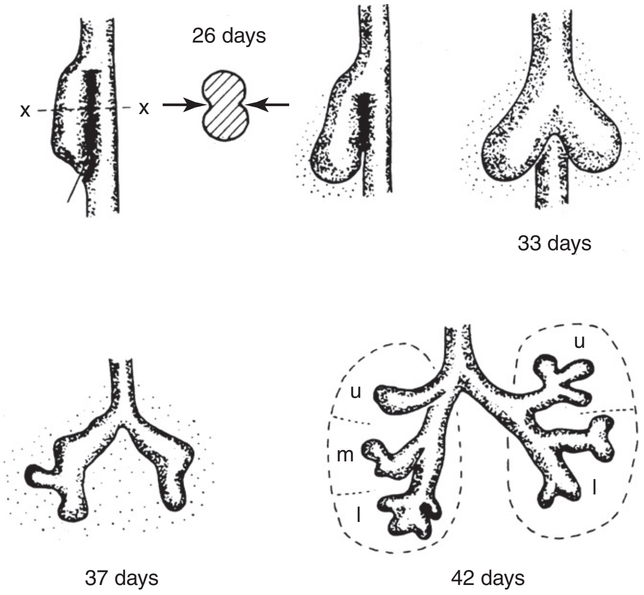

Figure 44–1. Embryonic lung development. At 26 days the lung first appears as a protrusion of the foregut. By 33 days the lung bud has branched, and by 37 days the prospective main bronchi are penetrating the mesenchyme. Airways to the lobar and initial segmental bronchi have formed by 42 days. *(Modified from Burri PW: Development and growth of the human lung. In Fishman AP, Fisher AB, editors:* Handbook of physiology: the respiratory system, *Bethesda, MD, 1985, American Physiologic Society, p 1, with permission.)*

Pseudoglandular Stage

The 15 to 20 generations of airway branching occur in the pseudoglandular period of lung development from about the 7th to the 18th week (Fig. 44-2). All airway branching to the level of the future alveolar ducts is complete. The developing airways are lined with simple cuboidal cells that contain large amounts of glycogen. There is some epithelial differentiation with the appearance of neuroepithelial bodies and cartilage by 9 to 10 weeks. Ciliated cells, goblet cells, and basal cells are in the proximal airways by 13 weeks. In general, epithelial differentiation is centrifugal in that the most distal tubules are lined with undifferentiated cells with progressive differentiation of the more proximal airways. Regulators of branching morphogenesis are FGF-10 and FGF-7 as well as endothelial growth factor, transforming growth factor-α, and other growth factors.[45] Upper lobar development occurs earlier than lower lobe development in animals, and a similar pattern of development probably occurs in humans. Early in the pseudoglandular stage, the airways are surrounded by a loose mesenchyme through which loose capillaries randomly spread. Pulmonary arteries grow in conjunction with the airways, with the principal arterial pathways being present by 14 weeks. Pulmonary venous development occurs in parallel but with a different pattern that demarcates lung segments and subsegments. By the end of the pseudoglandular stage, airways, arteries, and veins have developed in the pattern corresponding to that found in the adult.

Canalicular Stage

The canalicular stage between 16 and 25 weeks' gestation represents the transformation of the previable lung to the potentially viable lung that can exchange gas (Fig. 44-3).[50] The bronchial tree has completely branched and respiratory bronchioles are forming. The three major events during this stage are the appearance of the acinus, epithelial differentiation with the development of the potential air-blood barrier, and the start of surfactant synthesis within recognizable type II cells.[10] The acinus in the mature lung is the tuft of airways and alveoli originating from a terminal bronchiole that includes about six generations of respiratory bronchioles, and alveolar ducts that alveolarize with maturation. This saccular branching is the critical first step for the development of the future gas exchange surface of the lung. The mesenchyme surrounding the airways becomes more vascular and more closely approximated to the airway epithelial cells (Fig. 44-4). Capillaries initially form as a double capillary network between future airspaces and subsequently fuse to form a single capillary. With fusion of the vascular and epithelial basement membranes, a structure comparable to the adult air-blood barrier forms. If the double capillary network fails to fuse, the infant will have severe hypoxemia resulting from alveolar-capillary dysplasia. The total surface area occupied by the air-blood barrier begins to increase exponentially toward the end of the canalicular stage with a resultant fall in the mean wall thickness and with an increased potential for gas exchange.

Epithelial differentiation is characterized by proximal to distal thinning of the epithelium by transformation of cuboidal cells into thin cells that line tubes. The tubes grow both in length and in width with attenuation of the mesenchyme, which is simultaneously becoming vascularized. During the canalicular stage, many of the cells would best be characterized as intermediary cells, because they are neither mature type I nor type II epithelial cells.[10] These epithelial cells develop attenuated extensions as well as some characteristics of mature type II cells such as lamellar bodies, supporting the concept that type I cells are derived from type II cells or intermediary cells that then further differentiate into type I cells. After about 20 weeks in the human fetus, cuboidal cells rich in glycogen begin to have lamellar bodies in their cytoplasm. The transcription factors TTF-1, FOXa1, FOXa2, and GATA 6 mediate type II cell differentiation.[48] The glycogen in type II cells provides substrate for surfactant synthesis as the lamellar body content increases. In the adult human lung, the thin type I cells occupy about 93% of the alveolar surface versus 7% for type II cells.[13] About 8% of the lung cells are type I cells and about 16% of lung cells are type II cells.

Saccular and Alveolar Stages

The saccular stage encompasses the period of lung development during the potentially viable stages of prematurity from about 25 weeks to term. The terminal sac or saccule is the distal airway structure that is elongating, branching, and widening until alveolarization is completed. Alveolarization is initiated from the terminal saccules by the appearance of septa in association with capillaries, elastin fibers, and collagen fibers (see Fig. 44-4). Shallow alveolar structures with crests (or septa) with elastin at the free margin of the crests

can be identified by 28 weeks' gestation in the human.[21] Alveolar number increases from about 32 weeks' gestation, and the term human lung contains between about 50 and 150 million alveoli.[21,32] For comparison, the adult human lung has about 500 million alveoli.[40] The most rapid rate of accumulation of alveoli occurs between 32 weeks' gestational age and the first months after term delivery (Fig. 44-5). The potential lung gas volume and surface area increases from about 25 weeks' gestation to term. This increase in lung volume, and the surface area of sacculi establishes the anatomic potential for gas exchange and thus for fetal viability. There is a wide range of lung volumes and surface areas at a given gestational age. Therefore the gas exchange potential of different fetuses at the same gestational age will be determined in part by the structural development of the lung.

Alveolarization progresses rapidly from late fetal to early neonatal life and may be complete by 1 to 2 years after birth (see Fig. 44-5). A number of factors that can stimulate or interfere with alveolarization have been identified (Box 44-1).[31] Chronic mechanical ventilation of preterm animals using

modest tidal volumes and low oxygen exposures interrupts both alveolarization and vascular development (Fig. 44-6).[11] Mechanical ventilation of the saccular lung disrupts elastin at the developing crests and induces an "arrest in development" characterized by lack of secondary crest formation and resulting in fewer and larger alveoli without much fibrosis or inflammation (Fig. 44-7).[6] Preterm infants who have died after long-term ventilation or after the development of bronchopulmonary dysplasia (BPD) also have decreased alveolar numbers and an attenuated microvasculature with less prominent airway injury and fibrosis than in the past.[4] Factors that likely contribute to this arrest of lung development include many of the components of care of preterm infants. Antenatal glucocorticoid treatments in monkeys and sheep cause thinning of the interstitium and an increased surface area for gas exchange with delayed alveolar septation. Postnatal glucocorticoid treatments of the saccular lung also interrupt alveolarization and capillary development. Hyperoxia or hypoxia and poor nutrition can interfere with alveolarization. In transgenic mice, overexpression of proinflammatory mediators in the pulmonary epithelium interferes with alveolar development. Antenatal lung inflammation associated with chorioamnionitis in sheep causes delayed alveolar and microvascular development.[31] Multiple factors may contribute to delayed alveolarization in preterm infants. Because lung growth following the completion of alveolarization is by increase in airway and alveolar size, any event that decreases alveolar number could impact lung function as the individual ages.

PULMONARY HYPOPLASIA

Pulmonary hypoplasia is a relatively common abnormality of lung development with a number of clinical associations and anatomic correlates.[33] Primary pulmonary hypoplasia is unusual and is likely caused by abnormalities of the transcription factors and growth factors that regulate early lung morphogenesis such as thyroid transcription factor-1 and FGF family members.[48] Severe forms of acinar aplasia that probably result from abnormal regulation of lung growth and development have been reported. Secondary pulmonary hypoplasia is associated with either a restriction of lung growth or the absence of fetal breathing (Box 44-2). Any reduction of the chest cavity by a mass, effusion, or external compression can impact lung growth. Lung hypoplasia can be minimal or severe. Severe pulmonary hypoplasia associated with renal agenesis and prolonged oligohydramnios is characterized by a decrease in lung size and cell number together with narrow airways, a delay of epithelial differentiation, and surfactant deficiency. Relatively short-term oligohydramnios caused by ruptured membranes in the 16th to 28th week of gestation also can result in pulmonary hypoplasia, the magnitude in general correlating with the severity and length of the oligohydramnios. Infants with congenital diaphragmatic hernia have more severe hypoplasia on the ipsilateral side than on the contralateral side, although the contralateral lung also may be hypoplastic. The lungs have fewer and smaller acinar units, delayed epithelial maturation, and an associated surfactant deficiency. In experimental models, tracheal occlusion in late gestation can reverse much of the pulmonary hypoplasia resulting from diaphragmatic hernia, but the occlusion induces a decrease in type II cells and surfactant deficiency.[30]

FETAL LUNG FLUID

The fetal airways are filled with fluid until delivery and the initiation of ventilation. Most of the information concerning quantitative aspects of fetal lung fluid is from the fetal lamb with sonographic and pathologic correlates available for the human. The fetal lung close to term contains enough fluid to maintain the airway fluid volume at about 40 mL/kg of body weight, which is somewhat larger than the FRC once air breathing is established.[35] The composition of fetal lung fluid is unique relative to other fetal fluids in the fetal sheep and most other mammalian species.[24] The chloride content is high (157 mEq/L), whereas the bicarbonate and protein contents are very low. In contrast, the bicarbonate and chloride concentrations in fetal lung fluid from the rhesus monkey are not different from plasma values, demonstrating species differences in ion composition of fetal lung fluid. The electrolyte composition is maintained by transepithelial chloride secretion with bicarbonate reabsorption. Fetal lung fluid contains little protein because the fetal epithelium is quite impermeable to protein. Active transport of Cl^- from the interstitium to the lumen yields a production rate for fetal lung fluid of 4 to 5 mL/kg per hour. Assuming the fetus is 3 to 4 kg, the daily production of fetal lung fluid is about 400 mL per day. Fetal lung fluid flows intermittently up the trachea with fetal breathing movements, and some of this fluid is swallowed while the rest mixes with the amniotic fluid. The pressure in the fetal trachea exceeds that in the amniotic fluid by about 2 mm Hg, maintaining an outflow resistance and the fetal lung fluid volume. The secretion of fetal lung fluid seems to be an intrinsic metabolic function of the developing lung epithelium because changes in vascular hydrostatic pressures, tracheal pressures, and fetal breathing movements do not greatly alter fetal lung fluid production rates.

Although normal amounts of fetal lung fluid are essential for normal lung development, its clearance is equally essential for normal neonatal respiratory adaptation.[39] Fetal lung fluid production can be completely stopped at term by vascular infusions of epinephrine at concentrations that approximate the levels of epinephrine present during labor. The epinephrine-mediated reversal of fetal lung fluid flux from secretion to reabsorption does not occur in the preterm lung. However, epinephrine-mediated clearance can be induced by pretreatment of fetal sheep with the combination of corticosteroid and triiodothyronine. Inhibition of prostaglandin synthesis with indomethacin in the fetus reduces the production of fetal lung fluid and urine. Fetal lung fluid production and fetal lung fluid volumes are maintained in the fetal sheep until the onset of labor. During active labor and delivery, fetal lung fluid volumes decrease, leaving about 35% of the fetal lung fluid to be absorbed and cleared from the lungs with breathing. Most of the fluid moves rapidly into the interstitial spaces and subsequently into the pulmonary vasculature, with less than 20% of the fluid being cleared by pulmonary lymphatics. The clearance of the fluid from the interstitial spaces occurs over many hours. Fluid clearance after birth results from active sodium transport via the epithelial sodium channel (ENaC), which can be blocked with amiloride.[22] See also chapter 34 Genetic ablation of the α subunit of the ENaC causes death in newborn mice because fetal lung fluid is not cleared from the lungs (Fig. 44-8). Glucocorticoids upregulate the messenger

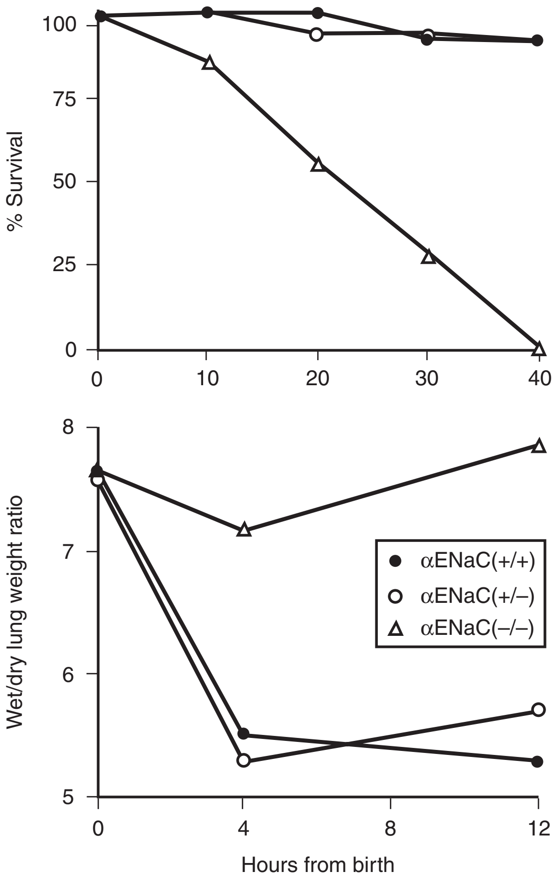

Figure 44–8. Ablation of the function of the α-epithelial sodium channel (ENaC) subunit prevents water clearance as indicated by the lack of decrease in the lung wet-to-dry weight ratio and results in neonatal death in mice. RNA (mRNA) for the EnaC subunits in the fetal human lung. Transient respiratory difficulties in many infants result from delayed clearance of fetal lung fluid.

SURFACTANT METABOLISM

Composition

Surfactant recovered from lungs of all mammalian species by alveolar wash procedures contains 70% to 80% phospholipids, about 10% protein, and about 10% neutral lipids, primarily cholesterol (Fig. 44-9). The phosphatidylcholine species of the phospholipids represent about 60% by weight of the surfactant and about 80% of the phospholipids. The composition of the phospholipids in surfactant is unique relative to the lipid composition of lung tissue or other organs. About 60% of the phosphatidylcholine species are saturated, meaning that both fatty acids esterified to the glycerol-phosphorylcholine backbone are predominantly the 16-carbon saturated fatty acid, palmitic acid. Most other phosphatidylcholine species in surfactant have a fatty acid with one double bond in the 2 position of the molecule. Saturated phosphatidylcholine is the principal surface-active component of surfactant, and much less saturated phosphatidylcholine is present in lipid fractions of lung not associated with surfactant metabolism. Thus saturated phosphatidylcholine can be used as a relatively specific probe of surfactant metabolism. The acidic phospholipid, phosphatidylglycerol, is present in surfactant in small amounts that vary between 4% and 15% of the phospholipids in different species (Table 44-1). Surfactant phospholipids from the immature fetus or newborn contain relatively large amounts of phosphatidylinositol, which then decrease as phosphatidylglycerol appears with lung maturity.[18] The switch from phosphatidylinositol to phosphatidylglycerol probably results from a fall in the circulating and lung tissue pools of free inositol in the fetus during late gestation. Phosphatidylglycerol is a convenient marker for lung maturity. The surfactant from the preterm lung is qualitatively inferior relative to surfactant from the mature lung when tested for in vivo function than is surfactant from term newborns.[26]

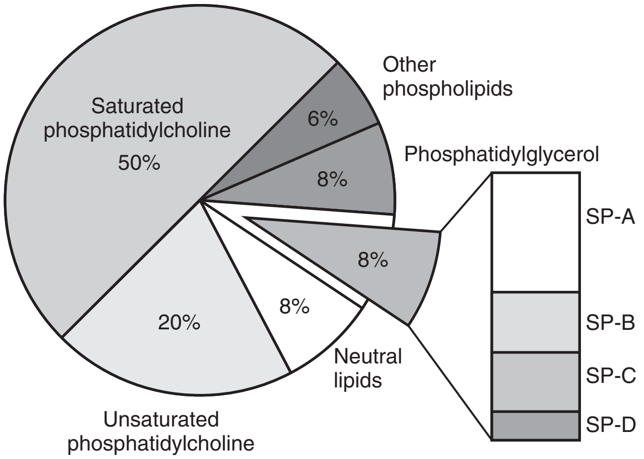

Figure 44–9. Composition of surfactant. The major component is saturated phosphatidylcholine. The surfactant proteins contribute about 8% to the mass of surfactant.

TABLE 44–1 Changes in Surfactant with Development

Surfactant function	Decreased	Normal

Four surfactant-specific proteins have been identified and their functions in part elucidated.[49] SP-A is a water-soluble collectin coded on human chromosome 10. The 24-kDa protein is heavily glycosylated in the carboxy-terminal region with blood group antigen as well as other carbohydrate moieties to yield a protein of about 36 kDa. SP-A has a number of isoforms because of the variable glycosylation. This protein has a collagen domain that permits SP-A monomers to form a collagen-like triple helix that then aggregates to form a multimeric protein with a molecular size of 650 kDa. SP-A contributes to the biophysical properties of surfactant primarily by decreasing protein-mediated inhibition of surfactant function. Mice that lack SP-A have no tubular myelin but have normal lung function and surfactant metabolism indicating that SP-A is not critical to regulation of surfactant metabolism. The major function of SP-A is as an innate host defense protein and as a regulator of inflammation in the lung. SP-A can both suppress and activate macrophage function under different test situations. SP-A binds to multiple pathogens such as group B streptococcus, *Staphylococcus aureus,* and herpes simplex type 1. The protein facilitates phagocytosis of pathogens by macrophages and their clearance from the airspace. SP-A can prevent influenza virus infection and decrease the inflammation caused by adenovirus. Patients with a deficiency of SP-A have not been identified. SP-A levels are low in surfactant from preterm lungs and increase with corticosteroid exposure. SP-A is not in surfactants used for treatment of RDS.

SP-B and SP-C are two small hydrophobic proteins that are extracted with the lipids from surfactant by organic solvents. These proteins contribute about 2% to 4% to the surfactant mass.[49] The SP-B gene is on human chromosome 2, and the primary translation product is 40 kDa. The protein is clipped to become an 8-kDa protein in the type II cell before it enters lamellar bodies for cosecretion with the phospholipids. SP-B facilitates surface absorption of lipids and the development of low surface tensions on surface area compression. Animals with antibodies to SP-B develop respiratory failure, and infants with a genetic absence of SP-B have lethal RDS after term birth. The genetic absence of SP-B is most frequently caused by a two base-pair insertion (121 ins 2) resulting in a frame-shift and premature termination signal resulting in a complete absence of SP-B. Multiple other mutations resulting in complete or partial SP-B deficiencies have been described.[38] (See also Part 3 of this chapter.) About 15% of term infants dying of a syndrome similar to RDS have SP-B deficiency. The lack of SP-B causes a loss of normal lamellar bodies in type II cells, a lack of SP-C, and the appearance of incompletely processed SP-C in the airspaces. These pro-SP-C forms are diagnostic of SP-B deficiency. Respiratory failure develops in mice that have less than about 20% of the normal amount of SP-B.

The SP-C gene is on chromosome 8, and its primary translation product is a 22-kDa protein that is processed to an extremely hydrophobic 4-kDa protein that is associated with lipids in lamellar bodies.[49] The mRNA for SP-C appears in cells lining the developing airways from early gestation. With advancing lung maturation, the mRNA for SP-C becomes localized only to type II cells. The sequence and cellular localization of the protein have been remarkably conserved across species; however, mice that lack SP-C have normal lung and surfactant function at birth. However, the mice develop progressive interstitial lung disease and emphysema as they age. Infants with a progressive interstitial lung disease resulting from a lack of SP-C are being reported, as are large kindreds of patients with the onset of interstitial lung disease at variable ages.[38] These patients generally do not have genetic alterations in the coding region of the protein, but do have dominant negative mutations that disrupt the processing of SP-C. The misprocessed SP-C results in SP-C deficiency in the airspaces and seems to also injure the type II cell. SP-B and SP-C probably work cooperatively to optimize rapid adsorption and spreading of phospholipids on a surface and to facilitate the development of low surface tensions on surface area compression. Surfactants prepared by organic solvent extraction of natural surfactants or from lung tissue contain SP-B and SP-C, but lack SP-A. Such surfactants are similar to natural surfactants when evaluated for in vitro surface properties or for function in vivo. Surfactant recovered from preterm animals has low amounts of SP-B and SP-C, which may, in part, explain its poor function.

The true incidences of genetic abnormalities of the surfactant system are not well known. A recent report of more than 300 term infants with severe RDS found about 14% had SP-B deficiency, and some infants had a new deficiency of the ATP-binding cassette transporter gene—*ABCA3*.[7] This *ABCA3* gene product is localized to lamellar bodies and functions as a lipid transporter. This clinical presentation is very much like SP-B deficiency. Some of the lethal RDS in term infants is explained by mutations in genes essential for surfactant metabolism. However, other infants probably have yet to be identified mutations in genes that disrupt other aspects of lung development as explanations for their respiratory failure.

SP-D is a hydrophilic protein of 43 kDa that is a collectin with structural similarities to SP-A.[49] It has a collagen-like domain as well as a glycosylated region that gives it lectin-like functions. This protein is synthesized by type II cells and Clara cells as well as in other epithelial sites in the body. Like the other SPs, its expression is developmentally regulated by glucocorticoids and inflammation. SP-D is a large multimer that functions as an innate host defense molecule by binding pathogens and facilitating their clearance. The absence of SP-D results in increased surfactant lipid pools in the airspaces and emphysema but no major deficits in surfactant function in mice. No humans with SP-D deficiency have been described.

Synthesis and Secretion

The type II cell is responsible for the major pathways involved in surfactant metabolism (Fig. 44-10). The synthesis and secretion of surfactant is a complex sequence of biochemical synthetic events that results in the release by exocytosis of the lamellar bodies to the alveolus. The basic pathways for the synthesis of phospholipids are common to all mammalian cells. Specific enzymes within the endoplasmic reticulum use glucose, phosphate, and fatty acids as substrates for phospholipid synthesis. The uniqueness of a phospholipid is determined by the character of the fatty acid side chains esterified to the glycerol carbon backbone and by the head group (e.g., choline, glycerol, and inositol) linked to the phosphate. Although the overall synthetic pathways are

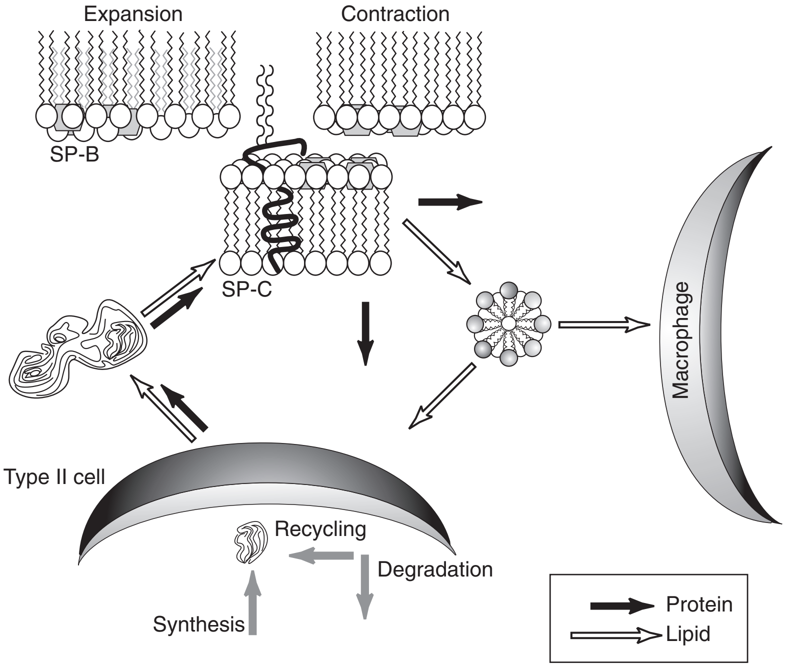

Figure 44–10. Surfactant metabolism in the type II cell in the alveolus. The lipid-associated surfactant proteins B (SP-B) and SP-C (*solid arrows*) track with the lipid from synthesis to secretion and surface film formation. The small vesicular forms of surfactant do not contain SP-B or SP-C.

known, the details of how the components of surfactant condense with SP-B and SP-C to form the surfactant lipoprotein complex within lamellar bodies remain obscure. Ultrastructural abnormalities of type II cells with SP-B deficiency and ABCA3 deficiency in term infants indicate that these gene products are critical to lamellar body formation.[7] If SP-B is absent, lamellar bodies are abnormal and SP-C is not processed correctly. Surfactant secretion can be stimulated by a number of mechanisms. Type II cells respond to β-agonists with increased surfactant secretion. Purines such as adenosine triphosphate are potent stimulators of surfactant secretion and may be important for surfactant secretion at birth. Surfactant secretion also is stimulated by mechanical stretch such as with lung distention and hyperventilation. The surfactant secretion that occurs with the initiation of ventilation following birth probably results from the combined effects of elevated catecholamines and lung stretch.

Surfactant Pool Sizes

Following the observation of Avery and Mead that saline extracts of the lungs of infants with RDS had high minimum surface tensions,[2] decreased alveolar and tissue surfactant pools were demonstrated in preterm animals. Increasing surfactant pool sizes correlate with improving compliances during development, although other factors such as structural maturation also influence compliance. Infants with RDS have surfactant pool sizes on the order of about 5 mg/kg of body weight. Preterm lambs with RDS can be managed with continuous positive airway pressure if their surfactant pool sizes exceed about 4 mg/kg. The quantity of surfactant recovered from the airspaces of infants with RDS is not much less than the amount of surfactant found in the alveoli of healthy adult animals or humans. However, much less surfactant is recovered from preterms than healthy term animals, who have surfactant pool sizes of about 100 mg/kg of body weight.[26] The large amount of surfactant in amniotic fluid in the human at term indicates that the term human fetal lung also has large pool sizes. Both the quantity and the quality of the surfactant from the preterm together with surfactant inhibition contribute to the deficiency state. The clinical observations that many preterm infants and animals respond remarkably to surfactant treatment supports the conclusion that in many infants surfactant deficiency is the primary problem. The endogenous pool sizes of surfactant that are sufficient for good lung function are lower than for treatment doses of surfactant, probably because the endogenous surfactant is optimally distributed and treatment doses of surfactant are not distributed uniformly at the alveolar level.

The rate of increase in the pool size of alveolar surfactant after preterm birth has been measured in ventilated preterm monkeys recovering from RDS (Fig. 44-11).[23] The surfactant pool size increased toward the 100 mg/kg value measured in term monkeys within 3 to 4 days. Although there is no comparable quantitative information for the human, Hallman and colleagues[19] measured the concentration of saturated phosphatidylcholine in airway suction samples from infants recovering from RDS and compared the results with values for infants without RDS and for surfactant-treated infants. The concentration of saturated phosphatidylcholine increased over a 4- to 5-day period to become comparable with values for normal or surfactant-treated infants. This slow increase in pool size is consistent with a clinical course of RDS of 3 to 5 days. The explanation for why surfactant pool sizes increase slowly after preterm birth is apparent from measurements of the kinetics of surfactant secretion and clearance in the newborn (Figs. 44-12 and 44-13). Following the intravascular injection of radiolabeled precursors of surfactant phosphatidylcholine, incorporation into lung phosphatidylcholine is rapid. However, there are long time delays between synthesis and the movement of surfactant components from the endoplasmic reticulum through the Golgi apparatus to

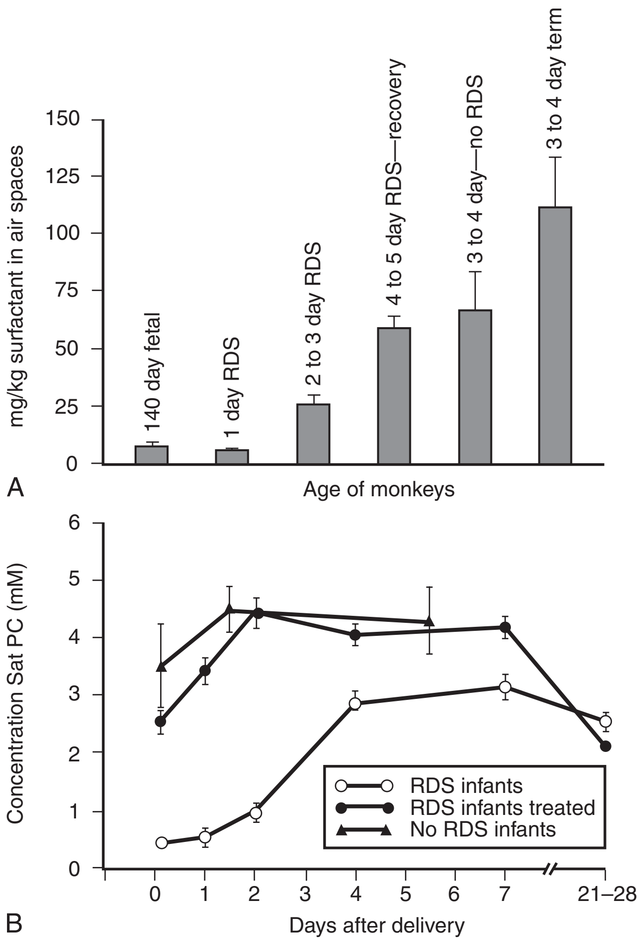

Figure 44–11. Changes in surfactant pool sizes with resolution of respiratory distress syndrome (RDS). **A**, The amount of surfactant recovered by alveolar lavage from monkeys with RDS and cared for with mechanical ventilation is shown relative to age and stage of the disease. **B**, The concentrations of saturated phosphatidylcholine (Sat PC) in airway samples from infants with RDS, infants with RDS treated with surfactant, and infants without RDS are graphed relative to age from birth. The concentration of Sat PC approached values for healthy preterm infants by 4 to 7 days. lamellar bodies for eventual secretion. The time lag from surfactant phospholipid synthesis to peak secretion of labeled surfactant is about 30 hours in ventilated preterm lambs with RDS.[28] These measurements of synthesis and secretion in animals were made using radiolabeled precursors of phosphatidylcholine and pulse labeling techniques not possible in preterm infants. However, phosphatidylcholine secretion was measured in preterm baboons and human infants with RDS using intravascular infusions of the precursors glucose and

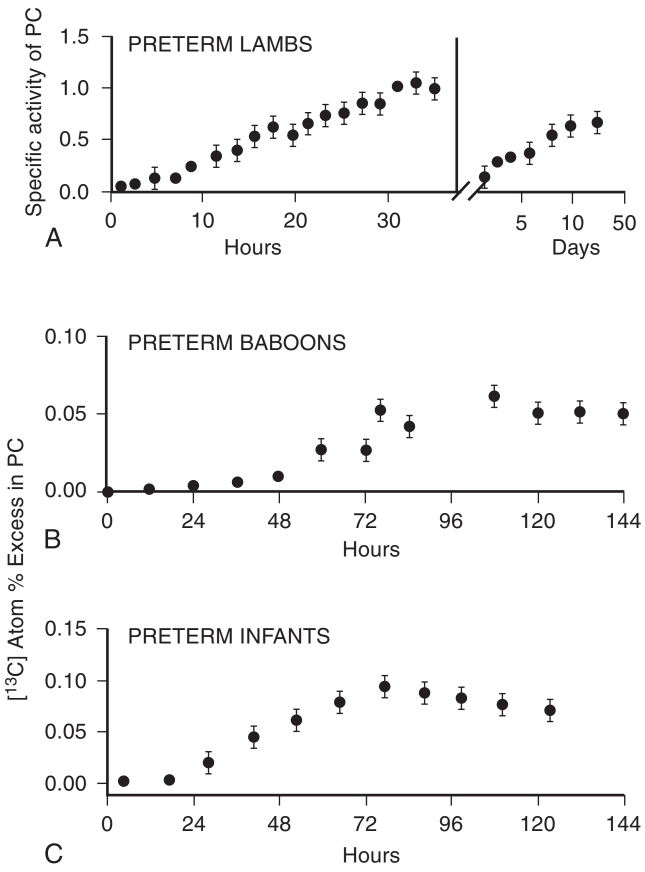

Figure 44–12. Time course of appearance of de novo synthesized surfactant phosphatidylcholine (PC) in the airways. **A**, Labeling of saturated phosphatidylcholine (Sat PC) in airway samples of ventilated preterm lambs given a single intravascular injection of [^{3}H]palmitic acid at birth and not treated with surfactant until about 38 hours of age. The discontinuity in the curve demonstrates the fall in the specific activity after treatment with surfactant (shown in days). **B**, Labeling of PC in airway samples of preterm surfactant-treated baboons that were ventilated for 6 days. The animals received [^{13}C]glucose by intravascular infusion for the first 24 hours of age, and the [^{13}C] in PC is expressed as [^{13}C]atom % excess. **C**, Labeling of PC in airway samples of preterm surfactant-treated mechanically ventilated infants with respiratory distress syndrome after intravascular infusion of [^{13}C]glucose for the first 24 hours of life. The label in the PC is expressed as atom % excess. palmitic acid labeled with stable isotopes.[8,9] The secretion kinetics of the stable isotopically labeled phosphatidylcholine are similar to the preterm lambs. There were lags of about 20 hours before glucose-labeled phosphatidylcholine was detected in the airway samples and peak enrichment of the stable isotope occurred at about 70 hours. There were delays between synthesis and secretion and the interval to peak airway accumulation of endogenously synthesized surfactant lipid is long in the preterm human.[12] In preterm ventilated baboons developing CLD, the percentage of the phospholipid that is secreted after synthesis is low relative to values measured in newborn or adult animals despite high accumulations of surfactant lipids in lung tissue.[44] The animals have an abnormality of processing and secretion of surfactant despite surfactant deficiency.

The slow secretion and alveolar accumulation of surfactant are balanced in the term and preterm lung by slow catabolism and clearance. Trace amounts of radiolabeled surfactant phospholipid given into the airspaces of term lambs are cleared from the lung with a half-life on the order of 6 days. The half-life measurements for infants with RDS made with stable isotope yield values of 3 to 5 days (see Fig. 44-13).[46] This slow lung clearance is in striking contrast to the more rapid catabolism characteristic of the adult lung with half-life values on the order of 12 hours. Preterm ventilated baboons that are developing CLD degrade a treatment dose of surfactant more rapidly with a half-life of about 2 days, suggesting that surfactant catabolic rates increase with lung injury.[44] Trace or treatment doses of radiolabeled surfactant given into the airspaces do not remain static in the airspaces. The surfactant phospholipids move from the airspaces back to type II cells, where they are taken up by an endocytotic process into multivesicular bodies. In the term and preterm lung, about 90% of the phospholipids are recycled back to lamellar bodies and resecreted to the airspace. In the adult lung, this process is perhaps only 50% efficient. The phospholipids are recycled as intact molecules without degradation and resynthesis.

The metabolic characteristics of surfactant phospholipids in the preterm are favorable for surfactant treatment strategies.[26] Alveolar and tissue pool sizes are small, and the rate of accumulation is slow. Treatment acutely increases both the alveolar and tissue pools because the exogenously administered saturated phosphatidylcholine is taken up into type II cells and processed for resecretion. The surfactants used clinically are not equivalent in function to native surfactant in the mature lung. However, within hours following surfactant treatment of preterm animals the surfactant recovered by alveolar wash has improved function, indicating that the preterm lung, if uninjured, can rapidly transform surfactant used for treatment with poor function to a good surfactant. Also of benefit is the slow catabolic rate of the lipid components of surfactant. This characteristic of the system means that the surfactant used for treatment remains in the lungs and is not rapidly degraded. Infants treated with surfactant can be extubated earlier if they maintain higher surfactant pool sizes.[47] Treatment doses of surfactant do not feedback-inhibit the endogenous synthesis of saturated phosphatidylcholine or the SPs. No adverse metabolic consequences of surfactant treatment on the endogenous metabolism of surfactant or other lung functions have been identified.

There is less information about the metabolism of the SPs in the preterm lung. SP-A, SP-B, and SP-C all seem to be recycled to some degree from the airspace back into lamellar bodies for resecretion with surfactant.[26] All three proteins have alveolar clearance kinetics that are similar to saturated phosphatidylcholine in the preterm lung. Therefore the critical surfactant components are conserved by recycling. The presumed function of the recycling pathways is to reassemble the components to regenerate biophysically active surfactant. SP-B and SP-C enter the lamellar bodies during their biogenesis in parallel with the phospholipids. In contrast, de novo synthesized SP-A is secreted independently of the lamellar bodies. This protein then associates with the phospholipids to form tubular myelin in the airspace. It is then recycled via lamellar bodies but with a lower efficiency than is saturated phosphatidylcholine. In the preterm ventilated baboon developing BPD, SP-A accumulates in high amounts in lung tissue and is minimally secreted, a pattern similar to that of phosphatidylcholine. Lung injury of the preterm results in abnormalities in surfactant metabolism and function.

Alveolar Life Cycle of Surfactant

After secretion as lamellar bodies, surfactant goes through a series of form transitions in the airspace.[26] The lamellar bodies "unravel" to form an elegant structure called *tubular myelin*. This lipoprotein array has SP-A at the corners of the lattice and requires at least SP-A, SP-B, and the phospholipids for its unique structure. Tubular myelin and other surfactant lipoprotein arrays are believed to be the reserve pool in the fluid hypophase for the formation of the surface film within the alveolus and small airways. Area compression of this film then squeezes out unsaturated lipid and some protein components of surfactant with concentration of saturated phosphatidylcholine in the surface film. New surfactant enters the surface film and "used" surfactant leaves in the form of small vesicles, which then are cleared from the airspaces. The major difference in composition between the surface-active tubular myelin and loose lipid arrays and the small vesicular forms is that the small forms contain little SP-A, SP-B, or SP-C. Although a complete surfactant contains multiple lipid and protein components, all of the components are not essential for biophysical function. Surfactants for treatment probably work well despite lacking some components of native surfactant.

Just preceding and following birth, lamellar bodies are secreted to yield an alveolar pool that is primarily lamellar bodies and tubular myelin. This surfactant then begins to function with aeration of the lung. As the newborn goes through neonatal transition, the percentage of surface active forms falls as the small vesicular forms increase. At equilibrium approximately 50% of the surfactant in the airspaces is in a surface-active form and 50% is in the inactive vesicular form. The vesicular forms of surfactant are believed to be the pools used for recycling of the phospholipid components of surfactant. The total surfactant pool size is not equivalent to the amount of active surfactant. In the preterm, conversion from surface active to inactive surfactant forms occurs more rapidly, probably because less SP is present. Pulmonary edema can further accelerate the process with the net result being a depletion of the surface active fraction of surfactant despite normal or high total surfactant pool sizes.

PHYSIOLOGIC EFFECTS OF SURFACTANT IN THE PRETERM LUNG

Alveolar Stability

Although alveoli have been traditionally considered to be independent spheres on which surfactant acts to stabilize their size, alveoli are polygonal in shape with flat surfaces and curvatures where the walls intersect. Furthermore, alveoli are interdependent in that their structure is determined by the shape and elasticity of neighboring alveolar walls. The forces acting on the pulmonary microstructure are chest wall elasticity, lung tissue elasticity, and surface tensions of the air-fluid interfaces in the small airways and alveoli. At functional residual capacity, the alveolus is open to atmospheric pressure. Although the surface tension of surfactant decreases with surface area compression and increases with surface area expansion, the surface area of an alveolus changes very little with tidal breathing. The low surface tensions resulting from surfactant help prevent alveolar collapse and keep interstitial fluid from entering the alveolus. Surfactant also keeps small airways from filling with fluid and causing luminal obstruction.[15] If alveoli collapse or fill with fluid, the shape of adjacent alveoli will change, which may result in distortion, overdistention, or collapse. When positive pressure is applied to a surfactant-deficient lung, the more normal alveoli tend to overexpand and the less normal (i.e., less surfactant) alveoli collapse, generating a nonhomogeneously inflated lung (Fig. 44-14).[41] Surfactant treatment can normalize alveolar size.

Pressure-Volume Curves

The effects of surfactant on the preterm surfactant-deficient lung are demonstrated by pressure-volume relationships during quasi-static inflation and deflation.[42] Preterm surfactant-deficient rabbit lungs do not begin to inflate until pressures exceed 25 cm H_2O (Fig. 44-15). The pressure needed to open a lung unit is related to the radius of curvature and surface tension of the meniscus of fluid in the airspace leading to the lung unit. In the collapsed lung, there are many different collapsed units with different radii. The units with larger radii and lower surface tensions "pop" open first because, with partial expansion, the radius increases and the forces needed to finish opening the unit decrease. The movement of fluid with high surface tensions in the airways causes very high sheer forces that can disrupt the airway epithelium.[27] With surfactant treatment, the fluid menisci in the airways have lower surface tensions that decrease the opening pressure from about 25 to 15 cm H_2O in this example with preterm rabbit lungs. The subsequent inflation is more uniform as

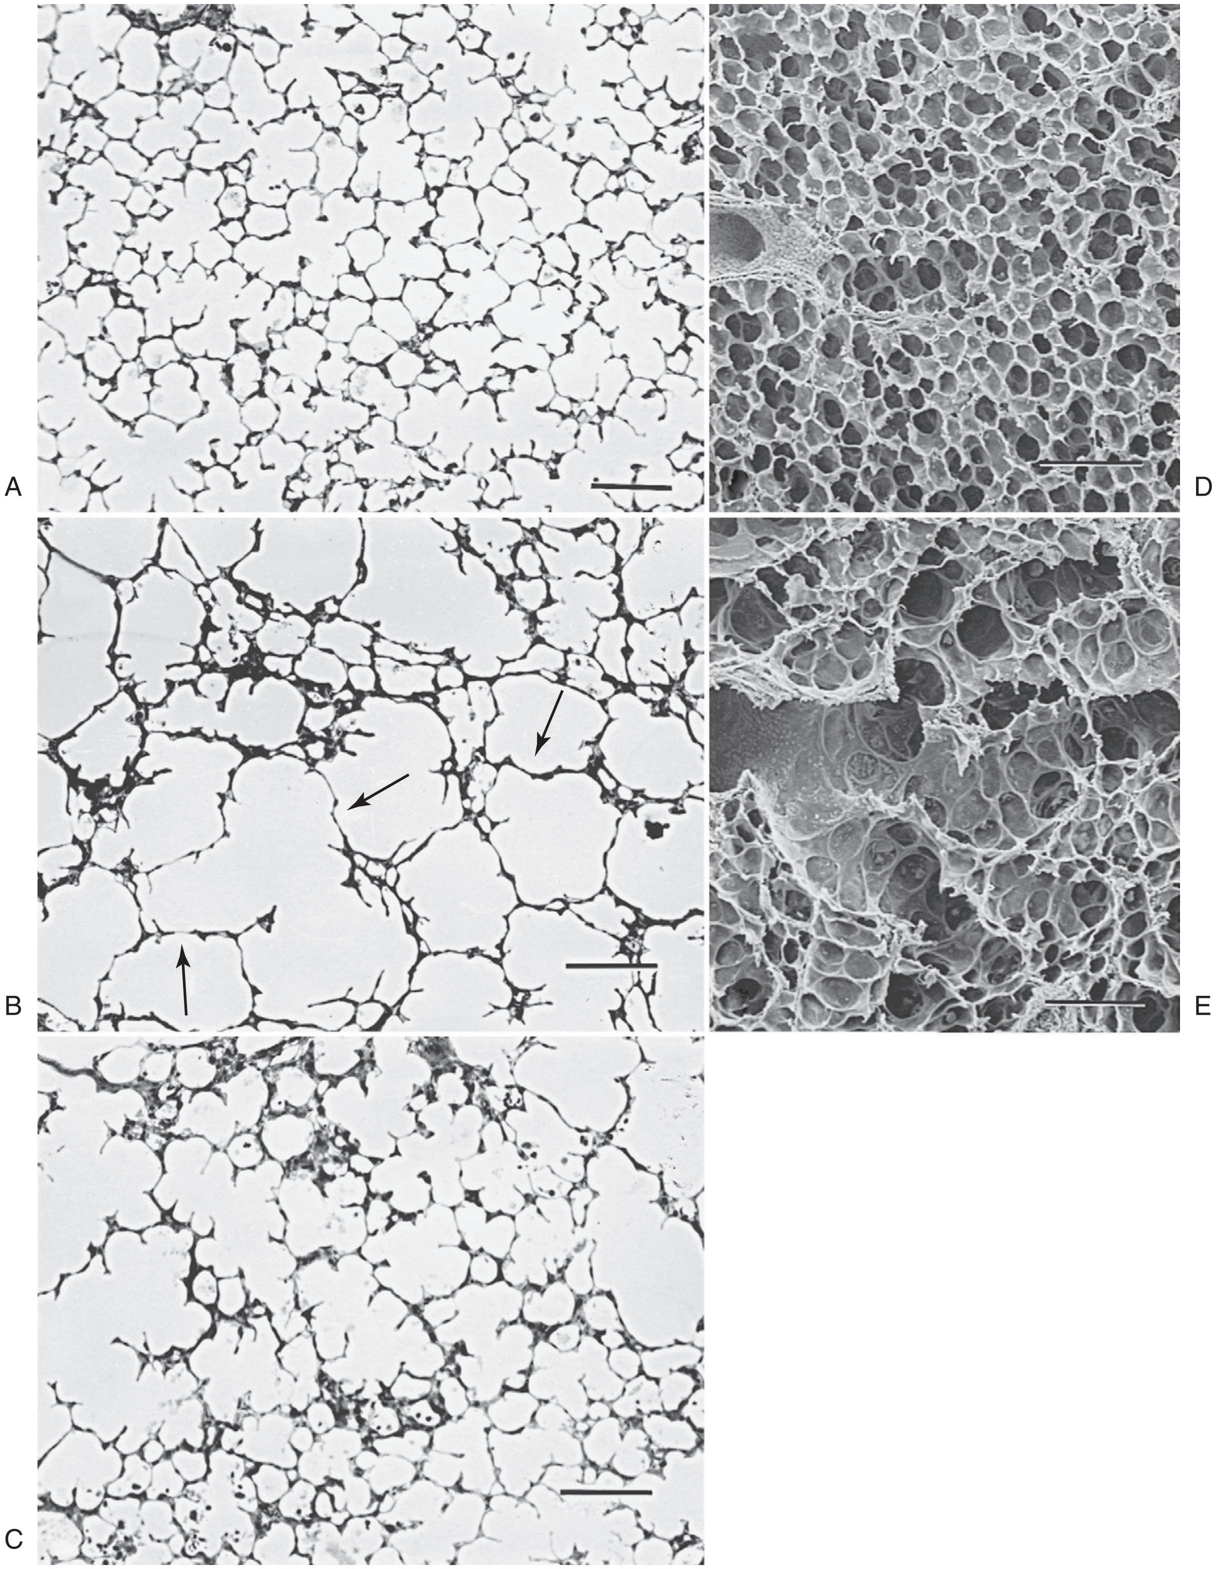

Figure 44–14. Ventilation of the preterm lamb lungs for 24 hours results in nonuniform alveolar inflation and dilation of alveolar ducts. Light microscopy in frames on left demonstrates uniform alveolar sizes in fetal lungs that have not been ventilated (**A**), dilated ducts and shallow alveoli *(arrows)* after 24 hours of ventilation (**B**), and a more normal-appearing lung following surfactant treatment at birth and ventilation for 24 hours (**C**). Scanning electron microscopy in the frames on the right taken at the same magnification demonstrates alveoli of uniform size in the unventilated lung (**D**) and dilated alveolar ducts with flattening of some alveoli and compression of others creating microatelectasis (**E**). Bar is 160 m. *(Modified from Pinkerton KE, et al: Lung parenchyma and type II cell morphometrics: effect of surfactant treatment on preterm ventilated lamb lungs,* J Appl Physiol *77:1953, 1994, with permission.)*

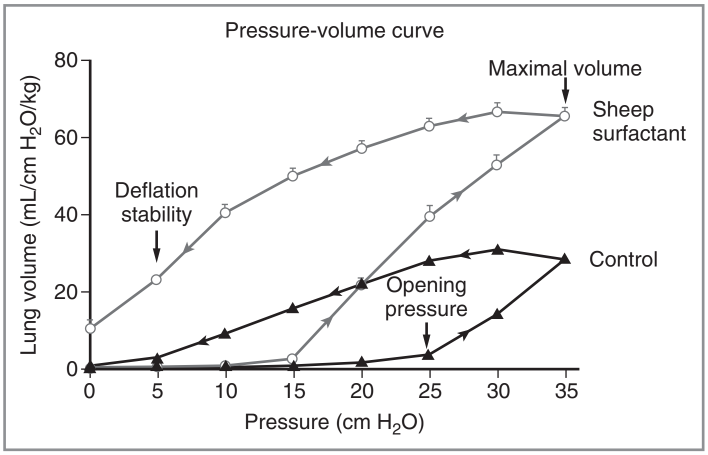
Figure 44–15. Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. The control lungs are from 27-day preterm rabbits. Surfactant deficiency is indicated by the high opening pressure, the low maximal volume at a distending pressure of 35 cm H_2O, and the lack of deflation stability at low pressures on deflation. In contrast, treatment of 27-day preterm rabbits with a natural surfactant alters the pressure-volume relationships. *(From Creasy RK, et al, editors:* Creasy & Resnik's maternal-fetal medicine, *6th ed, Philadelphia, 2009, Elsevier, p 201.)*



more units open at lower pressures, resulting in less epithelial injury and overdistention of the open units.

A particularly important effect of surfactant on the surfactant-deficient lung is the increase in maximal volume at maximal pressure. In the example in Figure 44-15, maximal volume at 35 cm H_2O is increased about 2.5-fold by surfactant treatment to a volume that is similar to that achieved in a term newborn rabbit lung. Pressures greater than 35 cm H_2O in control lungs result in lung rupture with little further volume accumulation. The opening pressures of many distal lung units in the surfactant-deficient lung exceed 35 cm H_2O and exceed the rupture pressure of the preterm lung. This volume difference resulting from surfactant treatment is lung volume that improves gas exchange because it is primarily parenchymal gas volume. Lung volume recruitment can be achieved rapidly with surfactant treatment. Another important effect of surfactant is the stabilization of the lung on deflation. The surfactant-deficient lung collapses at low transpulmonary pressures, whereas the surfactant-treated lung retains about 40% of the lung volume on deflation to 5 cm H_2O. This retained volume is equivalent to the total volume of the surfactant-deficient lung at 30 cm H_2O and demonstrates how surfactant treatments increase the functional residual capacity of the lung.

Dynamic lung mechanics also are altered by surfactant treatments. Time constants for deflation increase, resulting in less effective lung emptying. The clinical correlate is that a surfactant treatment may increase the FRC of infants with RDS by two mechanisms: the improved deflation stability and the longer expiratory time constant. The consistent initial response of infants with RDS to surfactant treatments is a rapid improvement in oxygenation, whereas improvements in PCO_2, compliance, and therefore ventilatory support variables tend to change more gradually. The explanation for improved oxygenation without changes in ventilation results from the acute increase in lung volumes following surfactant treatments.

LUNG MATURATION AND LUNG MATURITY TESTING

Surfactant Appearance with Development

Lamellar bodies first appear within type II cells by 20 to 24 weeks' gestation in the human fetus, and the amount of saturated phosphatidylcholine increases in lung tissue to term. This early presence of surfactant within human fetal lung tissue is consistent with the clinical experience that some infants born as early as 24 weeks' gestation have little lung disease. Lung maturity in the human fetus is generally present after 35 weeks' normal gestation. Therefore, an 11-week window of "early maturation" is possible for the human, at least in part because the surfactant synthetic and storage machinery is present and inducible in the human early in gestation.

The tests for fetal lung maturation depend on amniotic fluid composition reflecting the status of surfactant in the fetal lung. The lung secretes fetal lung fluid and any surfactant released into that lung fluid throughout late gestation. The flow of fluid out of the lung is episodic, and the balance between swallowing or loss of fetal lung fluid to the amniotic cavity is controlled by the larynx. The amniotic fluid can be characterized as the fetal cesspool, containing all fetal excretions as well as desquamated cells and other biologic matter. In normal pregnancies any test of gestational age or general fetal maturation, independent of which organ is targeted, correlates well with the degree of fetal lung maturity because maturational events are normally linked closely with gestational age. A remarkable aspect of the human fetus is the extraordinary inducibility of lung maturation at gestational ages as early as 24 weeks. Tests of lung maturation have been developed to identify fetuses with early lung maturation.

The L-S ratio introduced by Gluck and associates in 1971 remains the standard against which other tests are compared.[16] It depends on the flow of fetal lung fluid into the amniotic fluid being sufficient to change amniotic fluid phospholipid composition in a timely manner relative to the fetal lung maturation. The results are expressed as the ratio of a lecithin (phosphatidylcholine) fraction (cold acetone precipitated to enrich for saturated phosphatidylcholine) to sphingomyelin. Sphingomyelin is a membrane lipid and is a nonspecific component of amniotic fluid not related to lung maturation. The sphingomyelin content per milliliter of amniotic fluid tends to fall from about 32 weeks' gestational age to term, whereas the lecithin content, a large part of which is from the fetal lung, increases. The use of the lecithin measurement standardized against an internal control, sphingomyelin, will correct for changes in amniotic fluid volume. A value of 2 is achieved by 35 weeks' gestation in the normal fetus. Empirically, RDS is unlikely if the L-S ratio is 2 or greater.[16] Values of 1.5 to 2 are “immature”; however, the risk of RDS is low. The incidence of RDS is high for ratios less than 1.

Surfactant from the mature lung contains other lipids and the SPs, each of which has a unique developmental profile as surfactant composition changes with development.[18] Phosphatidylglycerol normally appears in amniotic fluid at the time of lung maturity at about 35 weeks’ gestation. Phosphatidylglycerol is absent from the amniotic fluid or tracheal aspirates of infants with RDS, and it appears in the lungs as the disease resolves. Phosphatidylglycerol can be detected before 30 weeks’ gestation in infants with early lung maturation. Phosphatidylglycerol is present in appreciable amounts only in lung tissue and surfactant. Therefore phosphatidylglycerol can be measured in amniotic fluid contaminated with blood or meconium. Numerous other tests for lung maturity have been developed. The TDx-FLM assay of the ratio of amniotic fluid surfactant to albumin seems to be equivalent to the L-S ratio for the prediction of RDS.[5] Clinical tests are less frequently used in clinical practice than in the past because virtually all women at risk of preterm delivery are treated with antenatal corticosteroids and the clinical decision to deliver a preterm seldom includes considerations of fetal lung maturation.

Although surfactant deficiency is the hallmark of RDS, other aspects of lung immaturity cause lung disease and morbidity. Lung structural immaturity may be clinically significant if the alveolar surface area has not developed sufficiently to sustain life or if airway immaturity results in pulmonary interstitial emphysema (PIE) and other severe air leak syndromes. The preterm lung is susceptible to oxidant damage and BPD if protective mechanisms have not developed. The surfactant deficiency component of lung immaturity can be corrected by surfactant treatment. Therefore the presence of surfactant may be a less critical factor in the clinical decision about whether to deliver preterm infants than in the past.

All tests of lung maturation are based on the premise that amniotic fluid accurately reflects the degree of differentiation of the type II cell population in the fetal lung. When the complexities of the pathway from surfactant synthesis in the fetal lung to its arrival in the amniotic fluid are considered, together with the multiple known effectors of the pathway, it is surprising that these tests are predictive in the evaluation of complicated pregnancies (Fig. 44-16). Amniotic fluid phospholipids are far downstream both in distance and time from the type II cell. As a generalization, developing animals require several days to process surfactant phospholipids from synthesis to secretion. Surfactant secretion and the flow of fetal lung fluid are influenced by preterm labor and delivery. The occurrence of preterm labor implies stress and elevated fetal catecholamine, cortisol, and prostaglandin levels. Epinephrine and selected prostaglandins cause surfactant secretion and decrease the flow of fetal lung fluid. Although the increased secretion should ultimately increase the L-S ratio, the secreted surfactant might not reach the amniotic fluid if fetal lung fluid ceased to flow. Changes in fetal breathing movements and fetal swallowing patterns also disrupt the normal egress of fetal lung fluid into the amniotic fluid. Finally, little is known about the turnover of surfactant phospholipids in amniotic fluid. Given the physiology and the complications introduced by pregnancy abnormalities and preterm labor, it is surprising that lung maturity tests usually are consistent with newborn outcomes.

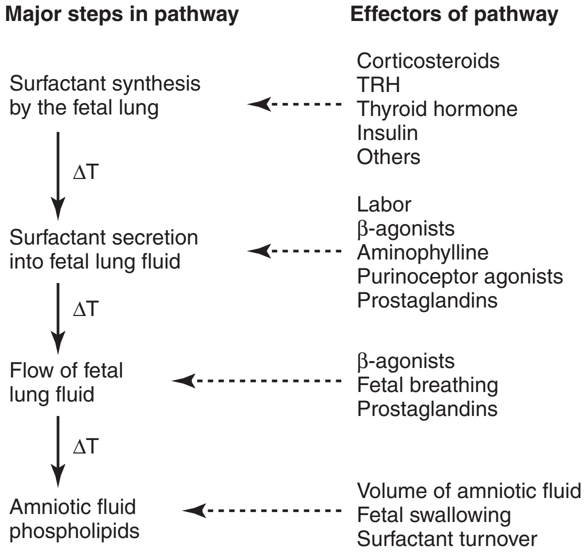


Figure 44–16. Pathway of surfactant from the fetal lung to amniotic fluid. The time relationships between surfactant synthesis and secretion and the amniotic fluid are not known even for the normal fetus. The figure indicates some of the factors that can modulate the events. *(From Jobe A: Evaluation of fetal lung maturity. In Creasy RK, et al, editors:* Maternal-fetal medicine: principles and practice, *Philadelphia, 1994, WB Saunders, p 423, with permission.)*

Induced Lung Maturation

Numerous clinical trials have documented that maternal corticosteroid treatments decrease the incidence of RDS by about 50%, and those infants with RDS tend to have less severe disease.[43] The decreased incidence of RDS needs to be interpreted within the context of maturational phenomena that occur spontaneously in the preterm. Most infants destined to deliver at term do not have mature lungs until about 36 weeks’ gestational age. However, only about 50% of infants born at 30 weeks’ gestational age have RDS. Although the incidence of RDS increases as gestational age decreases, some infants at 24 to 25 weeks’ gestational age have functional lung maturity. This spontaneous early lung maturation in the human fetus is believed to result from stress-induced maturation events that can be maternal, placental, or fetal in origin. Although specific abnormalities related to prematurity have been associated with early maturation, recent epidemiologic data do not support induced lung maturation with fetal growth restriction, preeclampsia, or prolonged preterm rupture of membranes. The changing epidemiology probably results from the more frequent use of antenatal glucocorticoids and a change in obstetric practices to delay preterm delivery as long as possible. Chronic infection and fetal exposure to inflammation is frequent in those pregnancies with preterm labor between 22 and 30 weeks' gestation.[17] Histologic chorioamnionitis was associated with a decreased incidence of RDS, and in experimental models, bacterial endotoxin or the proinflammatory cytokine interleukin-1 (IL-1) induces lung maturation when given by intra-amniotic injection.[31] Fetal proinflammatory exposures induce striking increases in surfactant and improvements in postnatal lung function after preterm delivery of lambs without increasing fetal cortisol levels. Therefore fetal exposure to inflammation may have the short-term benefit of decreasing RDS, but longer term effects such as increased incidences of BPD and periventricular leukomalacia are concerning. Prematurity cannot be considered a normal condition. It is useful to think of the infant with RDS as the normal unstressed preterm, whereas the preterm without RDS has experienced a stress sufficient to induce lung maturation.

The events resulting in spontaneous early lung maturation in the human have not been well characterized. Explants of human lung at 14 to 20 weeks' gestational age differentiate in organ culture in the absence of hormonal stimuli, and agents such as corticosteroids and thyroid hormones accelerate maturation.[36] Several agents, such as insulin and transforming growth factor-β, tend to block lung maturation, and androgens delay maturation. Because about half of corticosteroid-treated fetuses do not seem to respond, it is reasonable to propose that fetal lung maturation normally is suppressed in favor of growth. If this suppression is released by stress-related signals, then the lung is susceptible to either endogenously mediated maturational signals or to exogenous effectors. Corticosteroids are one of the categories of agents that can influence lung maturation; however, many other agents also can influence lung maturation. The inducing agents can act additively or synergistically in terms of both the timing and the magnitude of the response in experimental models.

The responses of the fetal lung to corticosteroids are multiple and impact many different systems that could influence the clinical outcome. The particular response depends on species, corticosteroid dose, and gestational age.[25] In general, corticosteroids induce lung structural maturation by increasing the surface area for gas exchange as is reflected by lung volume measurements. Type II cell maturation has been noted primarily in vitro. Biochemical markers of maturation include glycogen loss from type II cells, increased fatty acid synthesis, increased β-receptors, and increased choline incorporation into surfactant phosphatidylcholine. In vivo, animals demonstrate improved lung function and survival. Corticosteroid treatment also decreases the tendency of the preterm lung to develop pulmonary edema. Although the primary effect of corticosteroids on the fetal lung is generally considered to be induction of surfactant synthesis, effects on enzymes in the synthetic pathway have not been consistently demonstrated, and surfactant pool sizes do not increase until more than 4 days after maternal glucocorticoid treatments in sheep.[25] Lung function can improve following corticosteroid treatments even if surfactant is not increased because of changes in lung structure. In preterm animal models, corticosteroid treatment changes the dose-response curve such that less surfactant is needed to cause larger clinical responses. Because of increased lung volume, corticosteroid-treated fetuses also have improved responses to postnatal surfactant. There are additive or synergistic effects between the corticosteroid-exposed lungs and surfactant treatments.

Antenatal corticosteroid treatment is now the standard of practice for pregnancies at risk of preterm delivery.[43] This therapy is effective and safe, although there is not long-term follow-up data for infants born before 28 weeks' gestation. Repetitive courses of antenatal glucocorticoids have been given at 7- to 10-day intervals, a practice based on the suggestion that the fetal benefit was lost after this interval.[25] Maternal glucocorticoid treatments at 7-day intervals in sheep cause fetal growth restriction but augment lung maturation. Randomized trials in women at risk for preterm delivery demonstrate modest benefit, but there is some concern about longer-term outcomes, especially for infants exposed to four or more antenatal doses of antenatal corticosteroids.[14] There is presently insufficient information for a strong recommendation about the use of repeated corticosteroid treatments.

The only other lung maturation strategy that has been extensively evaluated clinically is the combination of corticosteroids and thyrotropin-releasing hormone (TRH). Thyroid axis hormones induce lung maturation and can act synergistically with corticosteroids in vitro. Thyroid hormones do not cross the human placenta efficiently, but the tripeptide TRH crosses to the fetal circulation and increases fetal thyroid hormone levels. Unfortunately, when evaluated in large randomized, controlled trials, TRH demonstrated no benefit and possible risks were identified.[1] Therefore, the use of TRH to supplement antenatal corticosteroid therapy is not recommended.

As noted earlier, fetal exposure to chorioamnionitis also can induce lung maturation. In experimental models, intra-amniotic endotoxin, or IL-1 will induce more striking lung maturation than will maternal corticosteroid treatments (Fig. 44-17).[3,29] The inflammatory mediators trigger lung maturation by direct contact with the fetal lung and induce a modest lung inflammation/injury response that resolves with large improvements in lung mechanics and increased surfactant lipid and protein pool sizes. Of clinical relevance, the maturational effects of maternal corticosteroids and chorioamnionitis seem to be additive for induced lung maturation.[37] The corticosteroids can suppress inflammation initially, but the inflammatory response is amplified in the fetal sheep at later times, perhaps because corticosteroids mature fetal innate immune responses. In clinical practice, ruptured membranes, a surrogate for chorioamnionitis, are not a contraindication to maternal corticosteroid treatment.[20]

This chapter focuses on the lung. However, maturation of other organs occurs in parallel in most fetuses. Other organs also are sensitive to corticosteroids and other agents. Maternal corticosteroid treatments not only decrease the incidence and severity of RDS but also decrease the incidence of patent ductus arteriosus, intraventricular hemorrhage, and necrotizing enterocolitis and increase kidney tubular function and postnatal blood pressure. Therefore, strategies to optimize maturation of the fetus at risk for preterm delivery target not only the lung but also other organs.

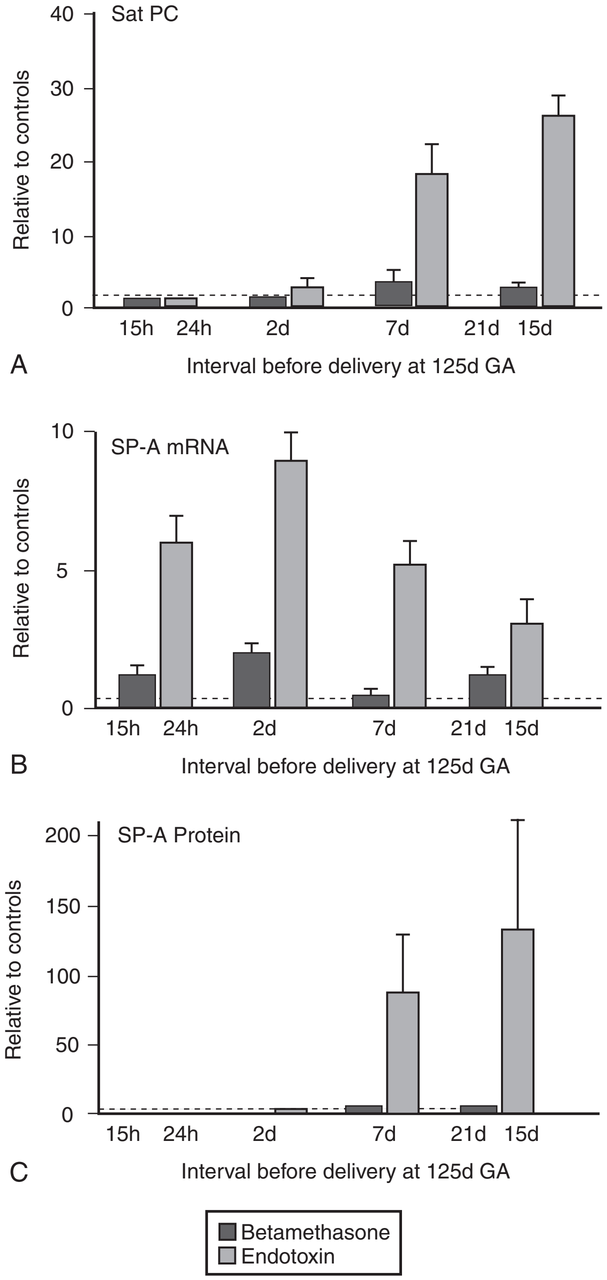

Figure 44–17. Intra-amniotic endotoxin increases the amount of saturated phosphatidylcholine (Sat PC) and SP-A more than maternal betamethasone in preterm fetal sheep. **A**, Although maternal betamethasone increased alveolar Sat PC 7 days and 21 days after treatment, the responses were less than for the fetal response to intra-amniotic endotoxin. **B**, SP-A mRNA increased more and stayed elevated following intra-amniotic endotoxin than in response to maternal betamethasone. **C**, Endotoxin exposure caused large increases in SP-A protein in the alveolar lavage. *(Data redrawn from Ballard PL, et al: Glucocorticoid regulation of surfactant components in immature lambs,* Am J Physiol *273:L1048, 1997; Zeltner TB, Burri PH: The postnatal development and growth of the human lung. PART 2

Assessment of Pulmonary Function

Waldemar A. Carlo and Juliann M. Di Fiore

Most neonates requiring intensive care present with respiratory symptoms. Although standard techniques for assessing pulmonary function can be applied in a healthy infant, special limitations and problems are encountered in very small or sick neonates. Methods have been developed to evaluate pulmonary function in neonates with suspected abnormalities of the cardiopulmonary system. This section presents a practical and clinical approach to disordered cardiopulmonary function and attempts to help distinguish between heart and lung disease.

CLINICAL OBSERVATIONS

Five common physical signs relay indirect information regarding pulmonary function: respiratory rate, retractions, nasal flaring, grunting, and cyanosis.

Respiratory Rate

Precise monitoring of respiratory rate is invaluable as deviations from the normal respiratory patterns have been observed with mechanical pulmonary dysfunction, acid-base imbalances, and arterial blood gas abnormalities. During spontaneous breathing, infants can only achieve successful gas exchange within a limited range of respiratory rates. At low rates, decreased alveolar minute ventilation may occur, while at high rates and corresponding low tidal volumes (V_T), a large proportion of the minute ventilation is wasted in ventilating dead space.

Infants may also adjust the respiratory rate to minimize work of breathing. The total work of breathing consists of elastic and resistive components. The elastic component represents the work required to stretch the lungs and chest wall during a tidal inspiration, and the resistive component is the work required to overcome friction caused by lung tissue movement and gas flow through the airways. Healthy infants rely on approximate respiratory rates of 40 to 60 breaths per minute and tidal volumes of 6 to 7 mL/kg. Infants with stiff lungs, such as those with respiratory distress syndrome (RDS), attempt to compensate for the increased workload with rapid shallow breathing, while patients with increased resistance (e.g., subglottic stenosis) usually exhibit slower and deeper breathing (Fig. 44-18).

Retractions

The neonatal chest wall is extremely compliant, and substernal, subcostal, and intercostal retractions are readily observable even with a relatively minor derangement in lung mechanics. Retractions are caused by negative intrapleural pressure–generated contraction of the diaphragm and other respiratory muscles and the mechanical properties of the lungs and chest wall. In neonates with respiratory distress, retractions become more apparent as the lungs become stiffer.

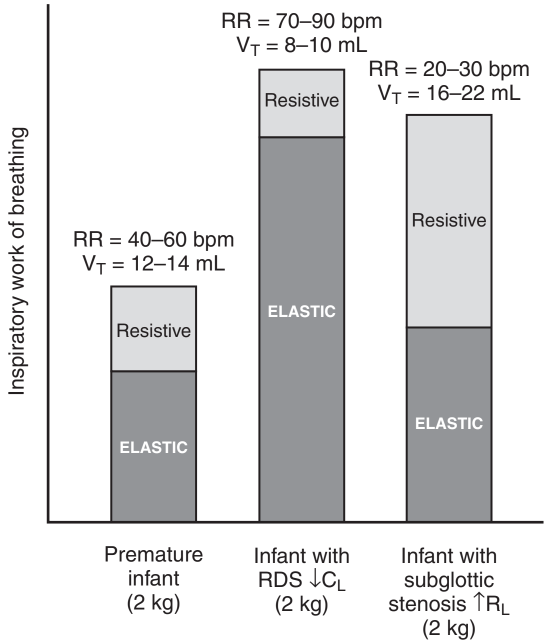

Figure 44–18. Relative contributions of the elastic and resistive components of the work of breathing in infants with normal pulmonary function, decreased lung compliance (C_L), and increased lung resistance (R_L). RDS, respiratory distress syndrome; RR, respiratory rate; V_T, tidal volume.

Apart from their characteristic appearance in RDS and other pulmonary diseases, severe retractions can signal complications of respiratory disease such as airway obstruction, misplacement of an endotracheal tube, pneumothorax, or atelectasis (see Part 4). Decreased retractions in the presence of adequate inspiratory effort suggest that lung compliance is improving.

Nasal Flaring

Nasal flaring is another sign of respiratory distress often observed in infants. The dilation of nostrils produced by contraction of the alae nasi muscles results in a marked reduction in nasal resistance. Because newborns are preferential nose breathers, and because nasal resistance contributes substantially to total lung resistance, nasal flaring markedly decreases the work of breathing. Nasal flaring is occasionally observed in the absence of other signs of respiratory distress, particularly during feeding and active sleep. Activation of other respiratory muscles, such as the genioglossus (tongue) and the laryngeal muscles, is also important for optimal function of the upper airways. The genioglossus muscle protrudes the tongue and, in part, maintains pharyngeal patency while the laryngeal muscles move the vocal cords and regulate airflow, particularly during expiration.

Grunting

With normal breathing, the vocal cords abduct to enhance inspiratory flow. In some respiratory disorders neonates attempt to close (adduct) their vocal cords during expiration. Expiration through partially closed vocal cords produces the grunting sound. During the initial phase of expiration, the infant closes the glottis, holds gas in the lungs, and produces an elevated transpulmonary pressure in the absence of airflow. During the last part of the expiratory phase, gas is expelled from the lungs against partially closed vocal cords, causing an audible grunt. During the expiratory phase, when the vocal cords are partially or completely closed, the ventilation-perfusion ratio ($\dot{V}/\dot{Q}$) is enhanced because of increased airway pressure and lung volume.

Grunting may be either intermittent or continuous, depending on the severity of lung disease. Grunting can maintain functional residual capacity (FRC) and partial pressure of arterial oxygen (PaO_2) equivalent to the application of 2 or 3 cm H_2O of continuous distending pressure. Because endotracheal intubation abolishes grunting, maintenance of lung volume with positive end-expiratory pressure (PEEP) is important following intubation.

Cyanosis

Central cyanosis, best observed by examining the tongue and oral mucosa, is an important indicator of impaired gas exchange. Clinical detection of cyanosis depends on the total amount of desaturated hemoglobin. Thus patients with anemia may have a low PaO_2 without clinically detectable cyanosis, and patients with polycythemia may be clinically cyanotic despite a normal PaO_2. Peripheral cyanosis may be normal in neonates but also occurs in situations of decreased cardiac output. The clinical features of cyanosis and their significance are discussed in detail in Chapter 45.

BLOOD GAS MEASUREMENTS

Maintaining optimal gas exchange is the primary function of the lung. Thus pulmonary evaluations should include blood gas estimates in addition to measurements of pulmonary mechanics. Both invasive and noninvasive blood gas measurements are available in the infant population. Blood gas measurements are the most widely used clinical method for assessing pulmonary function in neonates and form the basis for diagnosis and management of cardiorespiratory disease. Changes in partial pressure of alveolar oxygen (PAO_2) and $PACO_2$ can identify disordered pulmonary function in various clinical situations. PAO_2 and $PACO_2$ values depend on the composition and volume of alveolar gas, the composition and volume of the mixed venous blood, and the mechanisms of pulmonary gas exchange impairment. Alveolar gas composition can be obtained from the equation

$$PAO_2 = PIO_2 - \frac{PACO_2}{R}\left[FIO_2 + \frac{1 - FIO_2}{R}\right]$$

where PIO_2 is partial pressure of inspired oxygen ($PIO_2 = FIO_2 \times$ [barometric pressure − water vapor pressure]). At sea level, barometric pressure is 760 mm Hg; at 100% humidity, water vapor pressure is 47 mm Hg. $PACO_2$ is the partial pressure of alveolar carbon dioxide, and R is the respiratory quotient (usually 0.8). The mechanisms of pulmonary gas exchange impairment include $\dot{V}/\dot{Q}$ mismatch, shunt, hypoventilation, and diffusion limitation. Appropriate matching of the alveolar gas with the mixed venous blood yields optimal gas exchange. Mixed venous blood composition and volumes are determined by the arterial blood gas content, cardiac output, oxygen consumption, and carbon dioxide production.

Techniques of blood gas determination in infants with RDS are discussed in Part 3. Gas exchange during assisted ventilation is discussed in Part 4. Acid-base physiology is discussed in Chapter 36.

Partial Pressure of Arterial Oxygen

Depending on the efficacy of gas exchange, the alveolar oxygen partial pressure (tension) tends to equilibrate with the mixed venous blood, resulting in the PaO_2, which determines the degree of oxygen saturation of hemoglobin. In addition to its chemical combination with hemoglobin, oxygen is also dissolved in plasma and red blood cells (RBCs). Most of the oxygen in whole blood is bound to hemoglobin (measured clinically as oxygen saturation), whereas the amount of dissolved oxygen is only a small fraction of the total quantity carried in whole blood.

The quantity of oxygen bound to hemoglobin depends on the PaO_2 and the oxygen dissociation curve (Fig. 44-19). The blood is almost completely saturated at a PaO_2 of 90 to 100 mm Hg. The flattening of the upper portion of the S-shaped dissociation curve makes it virtually impossible to estimate oxygen tension greater than 60 to 80 mm Hg by using arterial oxygen saturation alone. The dissociation curve of fetal hemoglobin (compared with adult hemoglobin) is shifted to the left, and at any PaO_2 less than 100 mm Hg, fetal blood binds more oxygen. The shift appears to be the result of the lower affinity of fetal hemoglobin for 2,3-diphosphoglycerate. Note that pH, $PaCO_2$, temperature, and diphosphoglycerate content influence the position of the dissociation curve.

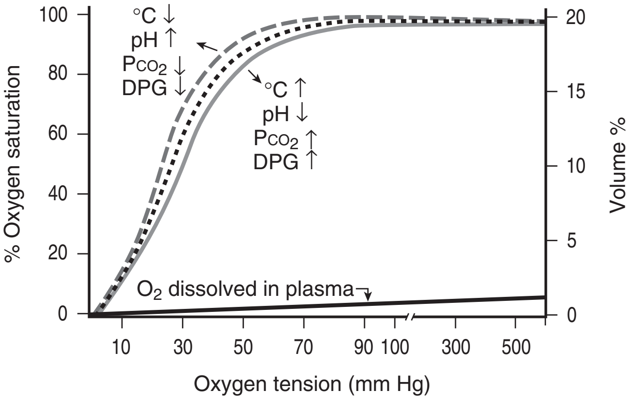

Figure 44–19. Factors shifting the oxygen dissociation curve of hemoglobin. (Fetal hemoglobin is shifted to the left.) *(From Martin RJ, et al: Respiratory problems. In Klaus M, et al, editors:* Care of the high-risk neonate, *Philadelphia, 1993, WB Saunders, p 228, with permission.)*

Arterial oxygen content (CaO_2) is the sum of hemoglobin-bound and dissolved oxygen, as described by the following equation:

$$CaO_2 = (1.37 \times Hb \times SaO_2) + (0.003 \times PaO_2)$$

where the arterial oxygen content is in mL/100 mL of blood, 1.37 is the approximate amount of oxygen (in milliliters) bound to 1g of hemoglobin at 100% saturation, Hb is hemoglobin concentration (g/100 mL), SaO_2 is the percentage of hemoglobin bound to oxygen, and 0.003 is the solubility factor of oxygen in plasma (mL/mm Hg). In this equation, the first term ($1.37 \times Hb \times SaO_2$) is the amount of oxygen bound to hemoglobin. The second term ($0.003 \times PaO_2$) is the amount of oxygen dissolved in plasma and red blood cells.

Most of the oxygen in the blood is carried by hemoglobin. For example, if an infant has a PaO_2 of 80 mm Hg, an SaO_2 of 99%, and a hemoglobin concentration of 15 g/100 mL, CaO_2 is the sum of oxygen bound to hemoglobin ([$1.37 \times 15 \times 99$]/100 = 20.3 mL) plus the oxygen dissolved in plasma ($0.003 \times 80 = 0.24$ mL). In this example, just over 1% of oxygen in blood is dissolved in plasma and almost 99% is carried by hemoglobin.

The partial pressure of oxygen in arterial blood not only depends on the ability of the lungs to transfer oxygen as determined by alveolar ventilation but also is largely influenced by the $\dot{V}/\dot{Q}$. For normal gas exchange, the ventilation and perfusion should be proportional. The ratio should be very close to 1:1; that is, for every milliliter of gas that passes the alveoli, there should be a proportional volume of blood in the pulmonary capillary bed. If the $\dot{V}/\dot{Q}$ is decreased (as in RDS), only partial oxygenation and CO_2 removal from the mixed venous blood will occur. Oxygen supplementation can largely overcome the hypoxemia when the $\dot{V}/\dot{Q}$ is decreased. If the $\dot{V}/\dot{Q}$ is high, as in overventilation, partial pressure of oxygen is increased slightly.

The mechanism of shunt becomes evident when blood bypasses the alveoli, as occurs in congenital cyanotic heart disease, persistent fetal circulation, or atelectasis. Oxygen supplementation does not prevent the hypoxemia produced by such a shunt. Hypoventilation (e.g., due to apnea) is a common cause of hypoxemia. Diffusion limitation can affect oxygenation slightly, but this mechanism is not a common cause of severe hypoxemia in neonates. Hypoxemia due to either hypoventilation or diffusion limitation usually can be treated easily with oxygen supplementation.

Three indexes can be used to estimate the degree of oxygenation derangement (see also Part 8). The *arterial-alveolar oxygen tension ratio* (PaO_2/PAO_2 or a/AO_2 ratio) has no units, decreases with worsening oxygenation, and can be obtained from the equation

$$P(a/A)O_2 = \frac{PaO_2}{PiO_2 - \frac{PACO_2}{R}\left[FiO_2 + \left(\frac{1 - FiO_2}{R}\right)\right]}$$

where R is the respiratory quotient. Because $[FiO_2 + (1 - FiO_2)/R]$ approximates 1.0 and $PACO_2$ approximates $PaCO_2$, the equation can be simplified as follows:

$$P(a/A)O_2 \sim \frac{PaO_2}{PiO_2 - \frac{PaCO_2}{R}}$$

The *alveolar-arterial oxygen tension gradient* ($PAO_2 - PaO_2$ or $AaDO_2$) is expressed in millimeters of mercury, increases with worsening oxygenation, and can be obtained from the equation

$$P(A\text{–}a)O_2 = PiO_2 - PACO_2\left[FiO_2 + \left(\frac{1 - FiO_2}{R}\right)\right] - PaO_2$$

or

$$P(A\text{–}a)O_2 \cong PiO_2 - \frac{PaCO_2}{R} - PaO_2$$

The *oxygenation ratio* is expressed in millimeters of mercury, decreases with worsening oxygenation, and can be obtained from the equation

$$\text{Oxygenation ratio} = \frac{PaO_2}{FiO_2}$$

The oxygenation ratio is less often used because it is subject to inaccurate assessment of the oxygenation derangement when $PaCO_2$ varies markedly.

Often it is necessary to correct the degree of oxygenation for the ventilatory support because oxygenation is strongly influenced by mean airway pressure ($\overline{P}aw$) during assisted ventilation. The oxygenation index (OI) is useful under these circumstances. The OI, which increases with worsening oxygenation or increasing $\overline{P}aw$, has units of centimeters of water per millimeters of mercury and can be obtained by the equation

$$OI = \frac{\overline{P}aw \times FiO_2}{PaO_2} \times 100$$

Partial Pressure of Arterial Carbon Dioxide

$PaCO_2$ is an important measure of pulmonary function in neonatal respiratory disease. Mechanisms responsible for impairment of pulmonary exchange of CO_2 include hypoventilation, $\dot{V}/\dot{Q}$ mismatch, and shunt. In addition, an increase in dead space, as occurs with alveolar overdistention or gas trapping, impairs CO_2 elimination. Because of the high solubility coefficient of CO_2, diffusion limitation rarely affects CO_2 exchange. As tissue levels of CO_2 increase above those of arterial blood, molecules diffuse into the capillaries and are transported in RBCs and plasma. Unlike the S-shaped dissociation curve for O_2, the relationship between CO_2 tension and content is almost linear over the physiologic range.

The initiation of ventilation with the first breath after normal delivery results in a rapid fall in $PaCO_2$ within minutes of birth. PaO_2 rises rapidly to levels of 60 to 90 mm Hg, although some degree of mismatching of $\dot{V}/\dot{Q}$ is evident in the first 1 to 2 hours of life. This is believed to be the result of intracardiac and pulmonary right-to-left shunting. More recent data in larger groups of infants have characterized the increase in oxygenation following birth by way of pulse oximetry, allowing for further differentiation between preductal and postductal levels (Fig. 44-20).[58] The speed with which pulmonary ventilation and perfusion are uniformly distributed is an indication of the neonate's remarkable capacity for maintaining homeostasis.

Noninvasive Blood Gas Measurements (See also Chapter 31)

CARBON DIOXIDE

Noninvasive estimates of CO_2 by end tidal or transcutaneous detectors provide a reasonable alternative to frequent blood gas sampling, allowing for continuous monitoring of CO_2

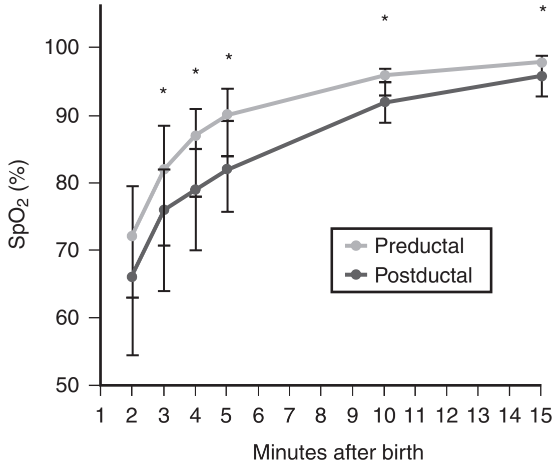

Figure 44–20. A rapid postnatal rise in oxygenation occurs during the normal fetal to neonatal transition. Preductal and postductal levels measured by way of pulse oximetry showed significantly lower postductal than preductal levels at 3, 4, 5, 10, and 15 minutes. *$P < .05$. (Mariani, et al: *Pre-ductal and post-ductal O_2 saturation in healthy term neonates after birth,* J Pediatr *150:418, 2007.)*

over prolonged periods of time. End-tidal has been shown to correlate well with arterial blood gases in term and preterm infants without pulmonary disease and can be useful for detection of rapid changes in exhaled CO_2 because data are displayed on a breath-by-breath basis.[62] However, with small tidal volumes and high respiratory rates it may underestimate the true alveolar gas in neonates. Transcutaneous CO_2 detectors have been shown to be superior to end-tidal CO_2 in ill neonates.[62] Yet sensor preparation, taping, and the need for changes in sensor location may limit its usefulness. Despite the limitations of end-tidal and transcutaneous monitoring of $CO_{2,}$ these methods provide critically important continuous information pertaining to changes in the respiratory system and minimize the need for blood gas analysis.

OXYGEN

Maintenance of oxygenation in an acceptable range requires constant monitoring that is not possible with intermittent blood gas measurements. This has led to the widespread implementation of pulse oximetry as a means of continuous noninvasive O_2 monitoring. See also part 3 Pulse oximetry measures the amount of hemoglobin molecules that are loaded with oxygen. It has a rapid response time and can be used as an estimate of PaO_2 for detecting short intermittent hypoxic episodes. However, as shown by the oxyhemoglobin dissociation curve (see Fig. 44-20), oxygen saturation levels should remain below 95% in infants requiring supplemental O_2 because hyperoxic values of PaO_2 cannot be distinguished beyond that range. With no current standards, ongoing multicenter trials are attempting to establish the optimal range for oxygenation in infants. Excessive levels of oxygen can result in retinopathy of prematurity, while low levels may increase vulnerability to intermittent hypoxic episodes. Recent data have shown a lower target range of oxygenation (85-89%), as compared with a higher range (91-95%), resulted in an increase in mortality and a substantial decrease in severe retinopathy.[81a] Completion of the multicenter trials should result in identification of these high and low alarm settings to minimize both hyperoxia and hypoxia in the preterm population. As results of these trials become published, implementation guidelines of the new standards will be needed; studies have shown varying levels of success in maintaining saturation values within a given range.[41,51] Studies combining pulse oximetry with automated adjustments in FiO_2 show promise in maintaining oxygen levels within the desired range, minimizing both hyperoxic and hypoxic events that are detrimental in this infant population.[17]

Hyperoxia-Hyperventilation Test

The hyperoxia test aids in differentiating between primary lung disease and congenital heart disease with right-to-left shunting. The test is performed by placing the infant in 100% oxygen for 5 to 10 minutes followed by monitoring oxygenation by arterial blood gas or noninvasive measures (see Part 3). In patients with primary lung disease, oxygen should diffuse into the poorly ventilated areas and improve oxygenation by 5 to 10 minutes of oxygen exposure. Persistent hypoxemia after this time period would suggest the presence of right-to-left shunting.

A modification of the hyperoxia test combining hyperoxia with hyperventilation can be used to distinguish between structural congenital heart disease and primary (or persistent) pulmonary hypertension of the newborn (PPHN), both of which have right-to-left shunting. Inhalation of 100% oxygen improves oxygenation in some patients with PPHN. In response to hyperventilation with 100% oxygen ($PaCO_2$ 25 to 30 mm Hg), more infants with PPHN achieve PaO_2 levels higher than 100 mm Hg. In contrast, patients with anatomically fixed right-to-left shunting rarely generate a PaO_2 well above 40 to 50 mm Hg, even with inhalation of 100% oxygen and hyperventilation (see Chapter 45).

Evaluation of Shunting

Desaturated blood from the right side of the heart enters the main pulmonary artery and crosses the ductus to the descending aorta when right-to-left ductal shunting occurs. Because the ductus almost always enters the aorta after the origin of the right subclavian and carotid arteries, blood arriving at these two sites is well oxygenated, whereas blood samples from the aorta and usually the left subclavian artery are less oxygenated if there is a right-to-left ductal shunt. Thus preductal gases can be obtained from the right radial artery, whereas blood in the descending aorta, and usually the left radial artery, is of postductal origin. Alternatively, placement of two pulse oximeters (one on the right hand and the other on the left hand or either foot) accomplishes the same effect in differentiating preductal and postductal PaO_2 or oxygen saturation.

Patients with PPHN sometimes have right-to-left shunting through the foramen ovale and the ductus arteriosus. Ductal shunting can be demonstrated by the presence of a simultaneous oxygenation gradient between preductal and postductal arterial blood, whereas foramen ovale shunting affects both preductal and postductal oxygenation. Echocardiography can be used to confirm foramen ovale and ductal shunts.

PHYSIOLOGIC MEASUREMENTS

Tests of cardiopulmonary function performed on sick neonates can assist in diagnosis and treatment. Radiographic evaluation of the chest is an integral part of the diagnostic evaluation of respiratory disorders and is discussed in Chapter 37. Measurements of central venous and pulmonary artery pressures could indirectly give useful information regarding pulmonary function but are rarely available in the clinical neonatal setting. Knowledge of pulmonary mechanics may be useful in identifying disease entities and guide treatments, while plots of airflow, volume, and pressure may provide additional information on a breath-by-breath basis.

Airflow

Many devices are available for estimating airflow in infants. Noninvasive devices can be used for extended periods, yielding qualitative measurements of airflow that are sufficient for cardiorespiratory monitoring. These include devices to estimate chest wall expansion using impedance, strain gauges, or respiratory inductance plethysmography and devices to estimate airflow at the nose by application of a thermistor or end-tidal CO_2 detector. These devices can give approximations of tidal volume and information regarding the presence or absence of airflow and, used in conjunction, can distinguish central from obstructive apnea.

Precise quantitative measurements of airflow needed for analysis of pulmonary mechanics require an alternative group of devices placed at the nose such as a pneumotachometer or hot-wire anemometer. The pneumotachometer is the gold standard for quantitative measurement of airflow. To accurately measure flow, all air must pass through the pneumotachometer. In a ventilated patient, the pneumotachometer can be attached to an endotracheal tube with leaks minimized by repositioning the infant, using a cuffed tube, or applying gentle pressure to the neck. In a spontaneously breathing infant, the pneumotachometer must be incorporated into a nasal or oral mask that is tightly sealed around the patient's nose and mouth.[2] The hot-wire anemometer may also become an alternate choice in the measurement of pulmonary mechanics as improvements in hot-wire anemometer design continue in terms of accuracy and response time.[73] After reliable measures of flow are acquired, the flow signal is integrated to calculate volume.

Lung Volume

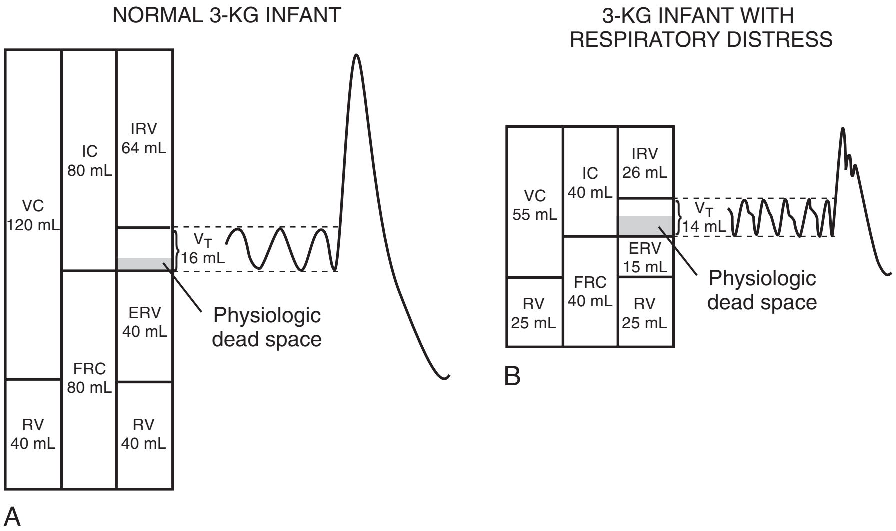
The total volume of gas in the lungs and airways can be measured and subdivided into various volumes (Fig. 44-21). The size of the lung compartments is related to the height, weight, and surface area of the subjects. FRC is the volume of gas in the lungs that is in direct communication with the airways at the end of expiration. The volume of gas in the FRC serves as an oxygen storage compartment in the body and a buffer so that large changes in alveolar gas tension are reduced. Helium dilution and nitrogen washout techniques have been adapted to measure FRC in infants.[33,34,75] The helium dilution technique uses the equilibration between a known volume and concentration of helium and the lung volume to be measured. After gas mixing and equilibration, FRC is calculated using the initial and final concentration of the helium and the initial volume of helium. Similarly, FRC can be estimated by measuring the volume of nitrogen washout from the lungs when nitrogen-free gas is inhaled.

Thoracic gas volume is the total volume of gas in the thorax at the end of expiration and, in contrast to FRC, includes gas that is not in communication with the airways (e.g., gas in pulmonary interstitial emphysema [PIE]). Thoracic gas volume is calculated by measuring pressure and volume changes during respiratory efforts against an occluded airway while the infant is inside a body plethysmograph.[57,70] With an inspiratory effort, the gas in the lungs expands, the lung volume increases, and the pressure or volume in the box increases. Because the product of pressure and volume is constant, the pressure changes in the box can be used to determine the lung volume changes, which, when analyzed with the pressure changes in the airway, yield the thoracic gas volume.

Tidal volume, the volume of gas in and out of the lungs during a single breath, can be measured either with a pneumotachometer or a plethysmograph. *Vital capacity* (the total gas capacity of the lungs) cannot be measured in infants because of lack of cooperation, but crying vital capacity, the V_T during crying, can be obtained.

One of the principal functions of the first breaths is to transform the fluid-filled fetal lung from a gasless organ to one with an appropriate FRC (see Chapter 26). The ability of the lungs to maintain a volume of gas at end-expiration depends on two factors. One is the chest wall, which acts as a support for the lungs, and the other is surfactant, which stabilizes the expanded alveoli. These two factors are not well developed in the premature infant.

The mechanisms responsible for initiation of breathing probably include both environmental and physiologic stimuli.



36	Respiratory rate/minute	70
0.3	Dead space/tidal volume ratio	0.6
5	Intraesophageal pressure diff. (cm H_2O)	18
4.4	Compliance (mL/cm H_2O)	1.0
29	Resistance (cm H_2O/liter/sec)	23
40	Total work/breath (gm cm)	111
1440	Total work/minute (gm cm)	7770

Figure 44–21. Partitioning of lung volumes and other measures of pulmonary function in a normal infant (**A**) and in an infant with respiratory distress syndrome (**B**).VC - Vital Capacity, RV - Residual Volume, IC - Inspiratory Capacity, FRC - Functional Residual Capacity, IRV - Inspiratory Reserve Volume, ERV - Expiratory Reserve Volume, VT - Tidal Volume. *(From Avery M, et al, editors:* The lung and its disorders in the newborn infant, *Philadelphia, WB Saunders, 1981, with permission.)*

After delivery the infant is exposed to cold and tactile environment. In addition, interactions occur between pH, P_{O_2}, and P_{CO_2}, whose contributions to inducing breathing in the human neonate have yet to be determined. Once initiated, the negative intrathoracic pressure of the first breath must overcome the effects of viscosity of fluid in the airway, surface tension, and tissue resistance. Radiographic studies of the lung indicate that inflation with air occurs immediately with the first breath. Transient retention of lung fluid might underlie transient tachypnea of the newborn (see Part 4). FRC is rapidly established, with little change throughout the first week of life.

Dead space, the portion of V_T not involved in gas exchange, varies with the incidence of areas of high $\dot{V}/\dot{Q}$. The dead space is divided into several compartments. *Anatomic dead space* is the airway volume not involved in gas exchange and is made up of the air passage from nares to terminal bronchioles. *Alveolar dead space* is the volume of gas in alveoli that are well ventilated but underperfused. Physiologic dead space is the sum of anatomic and alveolar dead space. In the normal newborn, physiologic dead space is 6 to 8 mL; smaller values are obtained in premature infants. The relationship of dead space to V_T is normally about 0.3. It is important to minimize the dead space added by apparatus for assisted ventilation or measurement of lung function to prevent rebreathing and inadvertent accumulation of carbon dioxide.

Pressures

Measurements of pressure that produce lung inflation are essential for pulmonary function testing. There are two ways to measure pressure, with the location of the measurement defining the system. Pressure can be determined by placing an esophageal balloon or catheter into the distal third of the esophagus. This measurement reflects pleural or alveolar pressure and is referred to as *transpulmonary pressure*. Transmission of pleural pressure can be compromised by chest wall distortion, which is common in preterm infants.[52] This problem can be resolved by catheter placement above the cardia but below the carina, which has been shown as a reliable measure of esophageal pressure transmission, independent of chest wall distortion.[18] The accuracy of this measurement should be verified by demonstrating the absence of a pressure gradient between the airway and esophageal pressure tracings during airway occlusion.

In the case of mechanically ventilated patients, pressure can be measured at the airway opening. This reflects pressure of the entire respiratory system. This is equivalent to pleural or alveolar pressure plus the pressure component due to the chest wall and is known as *transrespiratory pressure*. Because transrespiratory pressure and corresponding measurements of respiratory mechanics will be greater than those using transpulmonary pressure, it is important to clarify the type of pressure measurement when making comparisons between studies.

Respiratory Mechanics

There are many algorithms for calculating resistance and compliance that include the Mead-Whittenberger technique, linear regression, nonlinear regression, the linear portion of the flow curve, and the occlusion technique. The most commonly used algorithm in commercial devices for infants is the multiple linear regression technique also known as the *equation of motion* or *the Rhor equation*.

The *equation of motion* defines the relationship between pressure, flow, volume, and the elastic, resistive, and inertial components of the respiratory system. It is represented as

$$P = \frac{1}{C} \times V + R \times \dot{V} + I \times \ddot{V}$$

where P is the pressure that produces lung inflation, C is compliance, V is volume, R is resistance, $\dot{V}$ is flow, I is inertance, and $\ddot{V}$ is acceleration. As the inertial component is considered negligible for clinical considerations, the equation of motion is further simplified with the inertial component often dropped from the equation. This equation assumes a linear relationship which is not the case in the preterm infant. Yet, although not optimal, as nonlinear models have not lead to improvements in clinically applicable values for respiratory mechanics, the equation of motion continues to be the mode of choice in the clinical and research setting.

Although the equation of motion allows for the simultaneous calculation of compliance and resistance, these parameters can also be analyzed independently with known measurements of flow, volume, and pressure (transpulmonary or transrespiratory).[50,66]

Compliance

Compliance is a measure of elasticity or distensibility (e.g., of the lungs, chest wall, or respiratory system) and is defined as

$$\text{Compliance} = \frac{\Delta\text{Volume}}{\Delta\text{Pressure}}$$

Elastance is the reciprocal of compliance. In neonates, lung compliance is the most important component because the chest wall is very distensible. Lung compliance is low at the initiation of the first breath even in normal newborns. With the establishment of breathing and with gradual clearance of lung fluid during the first 3 to 6 hours after birth, FRC increases with concomitant improvement in lung compliance. Pathophysiologic factors that can increase the amount of fluid or impede the clearance of lung fluid could delay this improvement. The variability of compliance values in the first 2 hours after birth, in part the result of physiologic variation, could account for the frequent observations of higher respiratory rates in some infants during this period.

In distressed infants in whom lung compliance is markedly reduced, the compliant chest wall poses a disadvantage in that, as the infant attempts to increase negative intrathoracic pressure, the chest wall collapses (retracts). In addition, the more compliant neonatal airways could predispose the preterm infant to airway collapse during expiration and result in distal gas trapping.

Lung compliance is a measure of the intrinsic elasticity of pulmonary tissue and is measured either dynamically or statically depending on the absence or presence of relaxation of the respiratory muscles. Dynamic lung compliance can be measured during spontaneous breathing using devices to measure V_T and esophageal pressure as described earlier.

With this method, dynamic lung compliance is calculated by dividing the change in VT by the corresponding change in esophageal pressure at points of no airflow (e.g., between end-inspiration and end-expiration). This is represented by the line drawn from point C to point A in Figure 44-22. End-inspiration and end-expiration are used as quasistatic points of reference for pressure equilibration. At high respiratory rates or increased levels of resistance, pressure does not equilibrate between these two points resulting in an underestimation of the true compliance under these circumstances.

Alternatively, static lung compliance can be calculated between points of no flow when the respiratory muscles are relaxed by employing occlusion of the airway. This allows for complete equilibration of pressure throughout the system. During the occlusion, static respiratory system compliance can be calculated by dividing the total exhaled volume by the pressure change during the occlusion minus the pressure at end-expiration (Fig. 44-23).[64] An important advantage of this technique is that it does not require an esophageal balloon to measure pressure.

Both dynamic and static compliance, using a single occlusion, assume that compliance is constant throughout the breath. This may not be the case during periods of lung disease or overdistention of the lung during mechanical ventilation. Under these conditions, dynamic compliance underestimates the true compliance. True changes in compliance throughout a breath can be determined by expanding the single occlusion technique to include multiple brief interruptions during the expiratory phase of a breath, also known as the *multiple-interruption technique* (Fig. 44-24).[15,28,76] Using this technique, a decrease in compliance can be seen with increasing pressure as the lung becomes overdistended. In mechanically ventilated infants, compliance measurements should be acquired at the same PEEP and peak inspiratory pressure (PIP) to obtain values at the same section of the pressure-volume curve.

Because lung elasticity depends on lung volume, changes in FRC can alter lung compliance. The degree of elasticity corrected for lung volume or patient size is called specific compliance.[35] Whereas specific lung compliance in the normal neonate (1 to 2 mL/cm H_2O per kilogram) is comparable to that of the adult when corrected for unit body weight, compliance of the chest wall is relatively much higher in infants.

In addition to compliance, expiratory occlusion can also be used to determine the lung volume above the relaxation volume of the respiratory system (see Fig. 44-23). Expiratory volume clamping is a modification of the occlusion technique in which exhalation is prevented during several breaths at increasing lung volumes.[40] After plotting the corresponding volumes and pressures acquired during each occlusion, the slope of the function represents the compliance of the respiratory system. In addition, the intercept along the volume axis represents the resting volume of the respiratory system.

Resistance

Pulmonary resistance is a measure of the friction encountered by gas flowing through the nasopharynx, trachea, and bronchi and by tissue moving against tissue. The basic definition of resistance states

$$\text{Resistance} = \frac{\Delta\text{Pressure}}{\Delta\text{Flow}}$$

Conductance is the reciprocal of resistance. Resistance depends on the airway caliber, tissue properties, and flow rate. In the full-term infant pulmonary resistance is around 30 cm H_2O/L per second, approximately six times higher than that in the adult. Both airway resistance (the resistance caused by the airways) and viscous resistance (the resistance caused by tissues) contribute to total pulmonary resistance. Because of the high resistance in infants, respiratory apparatus with low added resistance should be used. An apparatus with a high resistance alters the same variables that are measured. A major site of airway resistance in the neonate is the upper airway, particularly the nares. The high resistance of the upper airway limits the ability to detect small changes in pulmonary resistance.

The pressure-volume and flow-volume loops generated from these waveforms can be used to calculate resistance. For

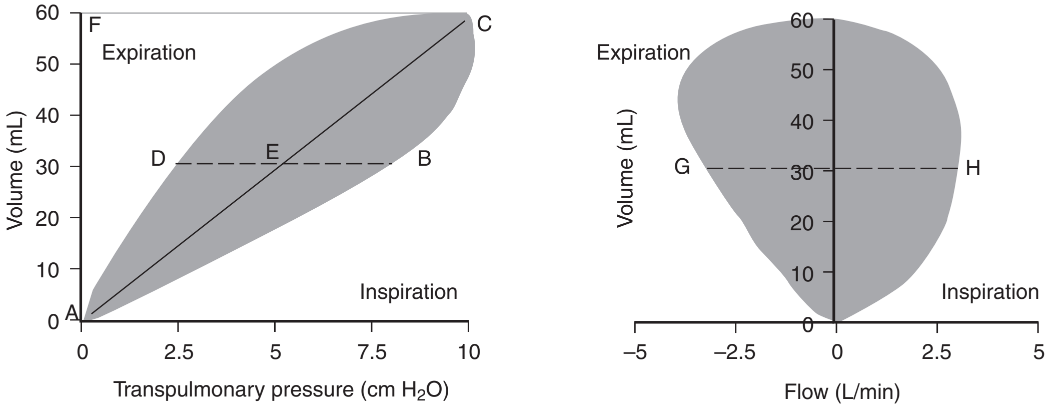


Figure 44–22. Dynamic lung compliance can be calculated as the Δ volume/Δ pressure as shown by the slope of line AC. Work of breathing is represented as the area inside the section drawn by ABCFA. Resistance can be calculated as the change in pressure, shown by the difference between points D and B, divided by the change in flow, shown by the difference between points G and H at the same mid-volume points.

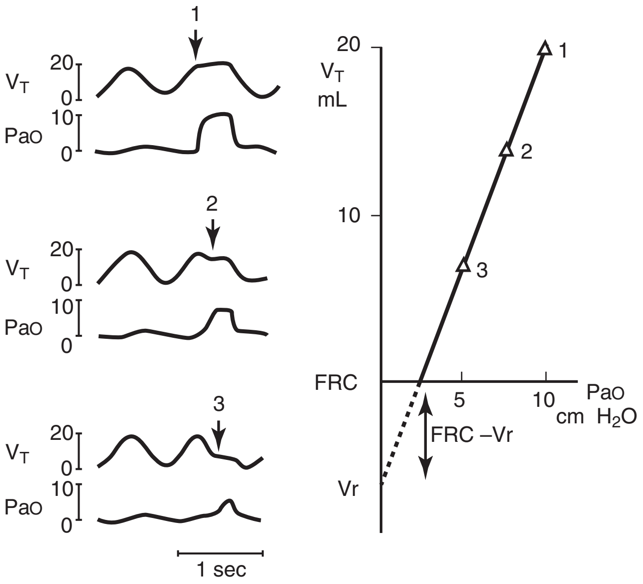

Figure 44–23. Schematic representation (from actual records) of the changes in lung volume (V_T in milliliters) and airway pressure (Pao in cm H_2O) during one spontaneous breath and occlusion of the airways during the expiratory phase of the following breath in a ventilated infant. In the three examples shown, occlusion is performed (from top to bottom) at end-inspiration, in the first third of expiration, and in the last third of expiration. After the occlusions (indicated by *arrows*), Pao gradually rises to a plateau, corresponding to the recoil value of the respiratory system at that lung volume. *Right*, Plot of the changes in lung volume above the end-expiratory level (FRC) against the corresponding changes in Pao as obtained in the left panel. The slope of the function represents the compliance of the respiratory system, the intercept on the Pao axis represents the internal recoil of the respiratory system at FRC, and the intercept of the V_T axis represents the resting volume of the respiratory system (Vr). *(From Mortola JP, et al: Measurements of respiratory mechanics in the newborn: a simple approach,* Pediatr Pulmonol *3:123, 1987. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)*

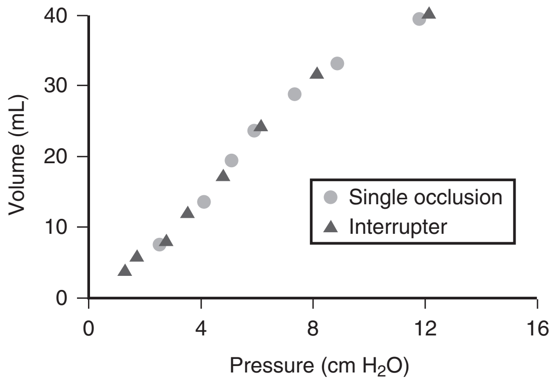

Figure 44–24. A typical example of the volume-pressure relationships obtained with both the interrupter and single occlusion techniques. Each point represents the compliance at that particular volume within the breath.

example, as shown in Fig. 44-22, the Mead-Whittenberger technique assesses resistance at midvolume by dividing the change in pressure between points D and B by the change in flow between points G and H. Resistance can be measured at additional volumes throughout the breath by using the occlusion or multiple-interruption technique as described earlier. In this case, resistance is calculated by dividing the pressure during the occlusion by the flow immediately preceding the occlusion (Fig. 44-25). These points of pressure and flow can be plotted to represent resistance over a range of volumes throughout the breath.[28] Furthermore, this technique can be used to partition the components of resistance into those due to airflow and those due to viscous tissue resistance.

At this point, three modes of calculating resistance have been discussed: the equation of motion, the Mead-Whittenberger technique, and the multiple-interrupter technique. The equation of motion uses linear regression to acquire the best fit corresponding to an average overall resistance for that breath. The Mead-Whittenberger technique gives the resistance for that same breath at only one point in time, midvolume (Fig. 44-26). The multiple-interrupter technique can be used to reveal changes in resistance within the breath by plotting the pressure and flow for each occlusion. These are important considerations when calculating resistance in that these techniques may result in different values of resistance for the same breath.

To understand why multiple techniques may result in conflicting values of resistance for the same breath, knowledge of flow patterns is needed. During periods of low pressure, the corresponding flow regimen is laminar and the assumption that resistance is constant throughout the breath holds true (see Fig. 44-26). Under these conditions the deviation amongst techniques is minimized. As the pressure increases further, the flow regimen changes from laminar to turbulent. At this point, the corresponding increase in flow is diminished. Further increases in pressure will reach the point of flow limitation where no additional increase in flow occurs. This is a common occurrence in both spontaneously breathing infants with lung disease and mechanically ventilated infants. During a turbulent flow regimen, resistance is no longer constant throughout the breath and is dependent on the technique used. These discrepancies in resistance values, due to various techniques and flow regimens, have severely limited the application of resistance as a diagnostic tool in the clinical setting.

Time Constant

The *time constant* of the respiratory system is the duration (expressed in seconds) necessary for a step (e.g., pressure or volume) change to partially equilibrate throughout the lungs. A duration equivalent to one time constant allows for 63% of the equilibration of the change. Although one time constant is not a very useful parameter in the clinical environment, five time constants are equivalent to the amount of time needed for 99% equilibration of the system. This value can be useful in areas of patient care such as mechanical ventilation (see Part 4).

The time constant of the respiratory system can be obtained from the flow-volume plot acquired during a passive exhalation. With this plot, the slope during the expiratory

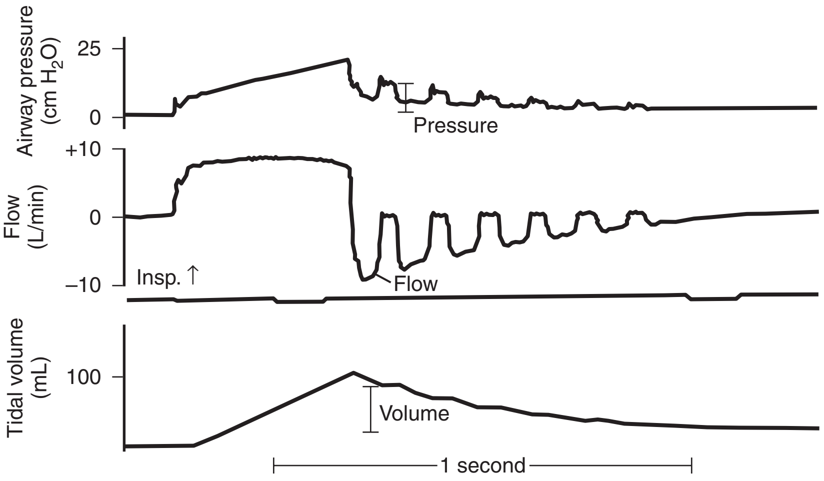

Figure 44–25. Illustration of data collected with the interrupter technique. The top channel is airway pressure proximal to the interrupter valve. The middle and bottom channels represent flow and volume, respectively. Compliance is calculated by dividing the volume above the end-expiratory level by the pressure during the occlusion. Resistance is calculated by dividing this pressure by the flow that preceded the interruption.

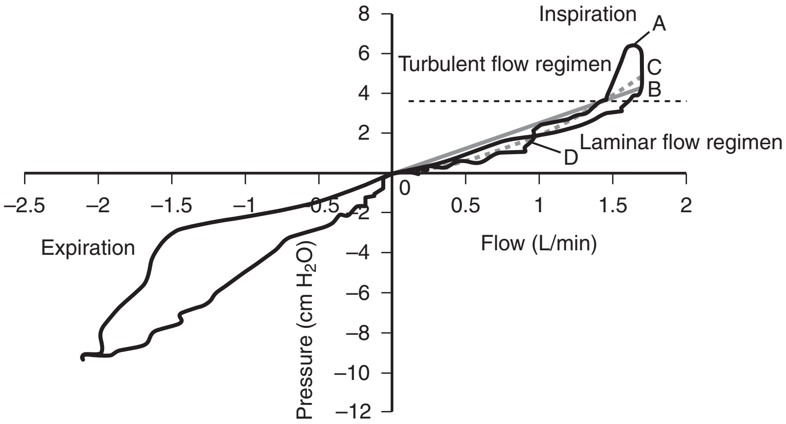

Figure 44–26. During a laminar flow regimen, resistance is constant throughout the breath and discrepancies between various techniques of measuring resistance are minimized. As the flow regimen changes from laminar to turbulent, resistance is no longer constant throughout the breath and becomes flow dependent. During this time, values of resistance between various techniques begin to diverge: Mead-Whittenberger (20 cm H_2O/L/sec; **A**) , linear regression (152 cm H_2O/L/sec; **B**), nonlinear regression (32 cm H_2O/L/sec; **C**), and the linear portion of the curve (106 cm H_2O/L/sec; **D**). *(Reproduced with permission from Di Fiore JM, et al: Respiratory function in infants. In Haddad G, et al, editors:* Basic Mechanisms of Pediatric Respiratory Disease, *Toronto, 2002, BC Decker, p 165.)*

phase of the breath is equivalent to the time constant of the respiratory system (Fig. 44-27). Calculation of the time constant using the flow volume curve assumes that the slope is linear throughout expiration. Flow limitation—as may occur with bronchoconstriction during expiration, postinspiratory activity of the respiratory muscles, or laryngeal adduction—can be identified by convexity toward the volume axis.[82] In this case, calculations of a single time constant are no longer valid. Although a numerical value for time constant cannot be accurately determined under these conditions, X-Y plots of flow and volume can be used to characterize pulmonary function. Normal and abnormal flow-volume loops can be used to identify infants with airflow limitation patterns (Fig. 44-28).[11,20,39] The maximal expiratory flow volume relationship can be measured in infants without the needed patient cooperation by using technology that produces a forced expiration. A respiratory jacket or cuff placed around the chest and abdomen can be suddenly inflated at the end of lung inflation to produce rapid thoracoabdominal compression and forced expiratory flow.[81] Alternatively, sudden exposure of the inflated lung to a negative pressure at the airway opening can be used to produce a forced deflation.[65] During this maneuver, peak expiratory flow, maximal flow

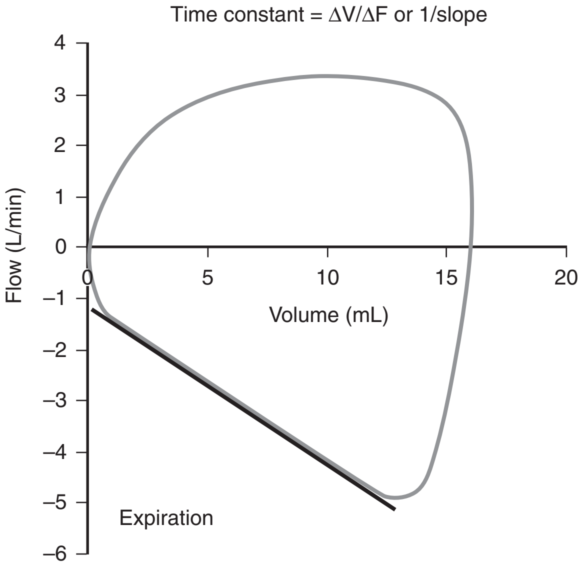

Figure 44–27. The time constant of a breath can be represented by the change in volume divided by the change in flow during the expiratory phase of the breath.

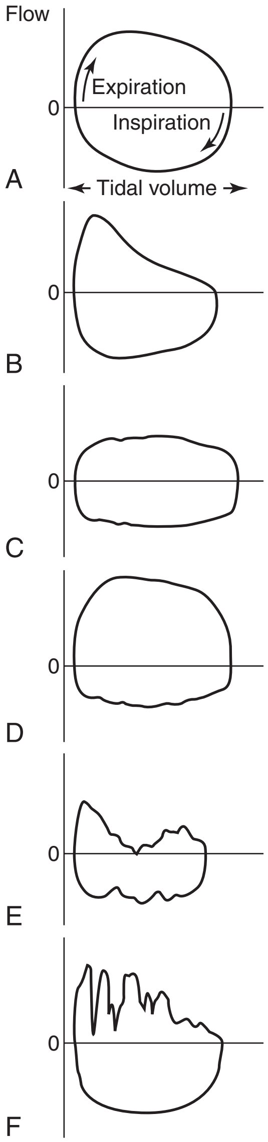

Figure 44–28. Examples of relationships between tidal flow and volume. Normal lemon-shaped loop (**A**); ski-slope loop observed with expiratory airflow limitation as seen in babies with bronchopulmonary dysplasia (BPD) (**B**); cigar-shaped loops observed in babies with extrathoracic airway obstruction with inspiratory and expiratory air flow limitation as seen in babies with subglottic stenosis or narrow endotracheal tubes (**C**); bun-shaped loop observed in babies with intrathoracic inspiratory airflow limitation as seen in babies with intraluminal obstruction (close to the carina) or an aberrant vessel compressing the trachea (**D**); crumpled loop as observed in babies with unstable airways or tracheomalacia (**E**); mountain-peaks loop is usually suggestive of an erratic airflow limitation as seen with airway secretions (**F**).

at FRC, and the patterns of flow-volume curves can be measured using a pneumotachograph. Flow-volume curves can be used to evaluate intrathoracic airway abnormalities and can detect flow limitation missed by the passive expiratory techniques.[81]

The time constant of the respiratory system can also be calculated without the use of the flow-volume curve using the relationship between the time constant, resistance, and compliance (see Part 4):

$$\text{Time Constant} = \text{Resistance} \times \text{Compliance}$$

Because both compliance and resistance are affected by different volumes and flows or by pulmonary disease, pulmonary mechanics change throughout the respiratory cycle and a single time constant may not always accurately represent lung mechanics.[71,79] However, for clinical purposes, linearity is assumed, and single values of compliance, resistance, and time constant usually suffice.[42]

Work of Breathing

The work of breathing is a measure of the energy expended in inflating the lungs and moving the chest wall. In general terms, work is the cumulative product of pressure and the volume of gas moved at each instant. In the normal infant, total pulmonary work has been determined to equal an average value of 1440 g/cm per minute. In an infant with respiratory distress, the total pulmonary work can increase as much as sixfold. This becomes most important when considered in terms of the oxygen cost of breathing. The neonate requires a higher caloric expenditure to breathe than does the adult, and the distressed infant requires an even higher caloric expenditure for this function. In the full-term infant, the work of breathing is minimal when the infant has a respiratory rate of 30 breaths per minute.

The pressure-volume and flow-volume loops generated from these waveforms can be used to calculate work of breathing as represented by the area inside the section drawn by ABCFA in Figure 44-22.

Limitations

Before any measurements of pulmonary function can be made, a clear understanding of equipment performance is needed. Although beyond the scope of this chapter, a clear adherence to these guidelines is imperative to ensure that lung function measurements can be performed with an acceptable degree of safety, precision, and reproducibility.[29] Once data are acquired, there are a multitude of algorithms for measuring pulmonary mechanics available. As no algorithm is ideal, standards are available addressing a range of issues from equipment criteria[29,30] to testing procedures.[9,63,77,79] A review of the techniques for measuring pulmonary mechanics and function has been published by the American Thoracic Society and the European Respiratory Society.[1]

Because various algorithms yield different results for the same breath, a wide range of published values for any given patient population has resulted, making it extremely difficult to define ranges for comparison between normal and diseased states. Compounding the issue is the large intrasubject variability of compliance and resistance.[38] In preterm infants, variability has been shown to range from 11% to 14% for compliance and 22% to 32% for resistance during spontaneous breathing with less variability (8% to 15% for compliance and 13% to 21% for resistance) during mechanical ventilation.

This is most likely due to muscle relaxation, and reduced fluctuations in respiratory rate and tidal volume compared with spontaneous respiration.

During mechanical ventilation, leaks around the endotracheal tube, a common occurrence in the neonatal intensive care unit setting, can result in overestimation of resistance and underestimation of elastance.[49] This error is minimized during the expiratory phase of the breath. A leak of less than 10% to 20% between the inspiratory and expiratory volume is generally considered acceptable to obtain reliable measurements of resistance and compliance.[49,54] Given these limitations, measurements of resistance and compliance during the expiratory phase of mechanical breaths with a leak of less than 10% should give the most precise and reproducible values.

Additional confounders that affect respiratory mechanics include sleep state,[69] posture,[10,16] endotracheal tube size,[56] FRC,[36] laryngeal braking,[36] gender,[80] race,[80] and respiratory patterns.[31] Errors in data calculation or interpretation can also occur if there are no compensatory modifications in mechanical ventilator settings in response to changes in lung function. For example, improvements in compliance at low pressures using the interrupter technique have been found in response to surfactant with no change in dynamic compliance.[14] This can occur due to overdistension of the lung as compliance improves in response to therapy if PIP is not decreased accordingly. As pressure-volume and flow-volume curves become more readily available on mechanical ventilators, they may become a useful tool, with or without measurements of respiratory mechanics, in distinguishing changes in pulmonary function. Figure 44-29 shows a simulation of a pressure-volume curve for a mechanically ventilated infant before and after surfactant administration with no change in peak inspiratory pressure. A numerical representation for dynamic compliance would show no change in compliance in response to surfactant administration. In contrast, visualization of the graph reveals improvement in compliance at low pressures but overdistension of the lung at high pressures as the peak inspiratory pressure was not decreased.

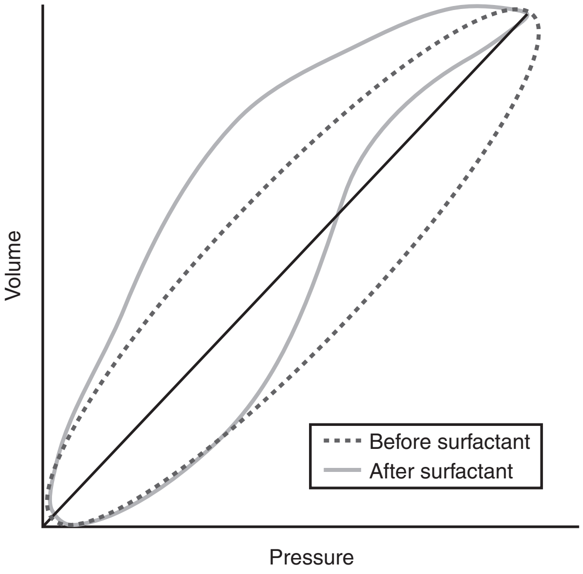

Figure 44–29. A representation of the change in compliance in response to surfactant administration. Note that dynamic compliance, as represented by the line, reflects no change. In contrast, visualization of the graph shows improvement in compliance at low volumes and overdistention of the lung, indicating the need to decrease peak inspiratory pressure.

CLINICAL APPLICATIONS

Even with these limitations, information about pulmonary mechanics may be useful for diagnosis and management of acute or chronic pulmonary disorders.[32,59,78] The goal of clinical care in terms of respiratory support is to optimize oxygenation and CO_2 elimination with the lowest possible ventilator settings to minimize lung injury. The use of pulmonary function testing can be a valuable tool in achieving this goal and reducing the incidence of barotrauma.[72] Visualization of pressure-volume curves and measurements of compliance can be used to assist in identification of excessive PIP or PEEP leading to lung overdistention[21,26,68] and to distinguish between alveolar collapse and overdistention to assist in determining the most advantageous PEEP.[4,8] High compliance and low resistance have also been shown to be associated with the likelihood of extubation success in infants recovering from RDS.[7]

Pulmonary function measurements have been used to assess mechanical effects of pharmacologic interventions. To optimize the response, changes in resistance have been used to compare treatment modalities with the meter-dosed inhaler and ultrasonic nebulizer being shown as superior modes of bronchodilator administration.[27] Although surfactant results in rapid improvement of gas exchange, early beneficial effects on respiratory mechanics have been shown in some studies[22,47,67] with other results not evident until 24 hours after dosing.[12,19] There has been interest in the effect of nitric oxide (NO) on respiratory mechanics and the incidence of chronic lung disease.[6,48,74] Although beneficial effects of NO are dependent on dose, time of administration, and disease severity,[6] there is currently no evidence that NO leads to improvement in respiratory mechanics.[3,23] However, infants who received inhaled NO for PPHN had maximal expiratory flows comparable to those who were treated with extracorporeal membrane oxygenation (ECMO) but lower flows than control subjects.[45] Furthermore, inhaled NO to prevent BPD has resulted in decreased need for bronchodilator therapy at 1 year of age.[43] Both postnatal and antenatal steroid use enhance lung function.[5,60] Recent data have shown the relevance of timing of treatment, with a diminished response to antenatal steroids if delivery occurs more than 7 days after therapy.[61] Lastly, diuretic administration has been shown to enhance lung function.[25,46] Interestingly, improvements in resistance and compliance did not always correlate with better oxygenation.[25]

Respiratory mechanics have also been employed in longitudinal studies to evaluate the clinical course of pulmonary diseases. The occurrence of meconium aspiration syndrome during infancy has been associated with alveolar hyperinflation and airway hyperreactivity to exercise at 7 ± 2 years of age.[24] Measurements of pulmonary mechanics at 1 year follow-up showed no difference between survivors in trials of high-frequency ventilation versus conventional ventilation.[44,83] Hypoxemic respiratory failure has been linked with an increased risk for impaired pulmonary function, particularly in the presence of congenital diaphragmatic hernia or ECMO.[55] Decreases in FRC, compliance, and conductance have been shown to be predictive of BPD,[13,37,53] with gradual improvements in this cohort as the lungs grow.[35] Because BPD is a manifestation of prolonged oxygen exposure or barotrauma, pulmonary function measurements and graphical displays may be most helpful in this area to minimize ventilator settings and duration of ventilatory support.

Even with the current limitations in methodology and confounders in the area of pulmonary function, diagnostic evaluations can be a useful tool in neonatal patient care. Ideally clinical evaluation should include both numerical values for resistance and compliance in addition to visualization of flow-volume, pressure-volume, and pressure-flow curves. Application of these tools for pulmonary function measurements should complement clinical assessment in the care of infants with pulmonary disorders.

PART 3

Pathophysiology and Management of Respiratory Distress Syndrome

Aaron Hamvas[*]

Enormous strides have been made in understanding the pathophysiology of respiratory distress syndrome (RDS) and more particularly the role of surfactant in its cause. Nevertheless, RDS, formerly referred to as hyaline membrane disease, remains a dominant clinical problem encountered among preterm infants.[3] The greatly improved outcome in RDS can be attributed primarily to the introduction of pharmacologic acceleration of pulmonary maturity and the development of surfactant replacement therapy.[9,29]

Because more of the sickest, most immature infants are surviving, the incidence of complications in the survivors of RDS remains significant. These include intracranial hemorrhage, patent ductus arteriosus (PDA), pulmonary hemorrhage, sepsis, and bronchopulmonary dysplasia (BPD), as discussed elsewhere in this textbook. It is often impossible to determine whether these disorders are the sequelae of RDS, of its treatment, or of the underlying prematurity. In this section the clinical features and evaluation of infants with RDS are discussed, and therapeutic approaches other than assisted ventilation are outlined.

INCIDENCE

RDS is one of the most common causes of morbidity in preterm neonates, although lack of a precise definition in infants with very low birthweight necessitates cautious interpretation of statistics regarding incidence, mortality, and outcome. The diagnosis can be established pathologically or by biochemical documentation of surfactant deficiency; nonetheless, most series refer only to a combination of clinical and radiographic features. Without biochemical evidence of surfactant deficiency, it is difficult to clinically diagnose RDS in infants with extremely low birthweight. The term *respiratory insufficiency of prematurity* has been widely used in some centers for infants who need oxygen and ventilator support in the absence of typical radiographic evidence of RDS.

RDS occurs throughout the world and has a slight male predominance. The greatest risk factors appear to be young gestational age and low birthweight (Fig. 44-30); however, late preterm delivery (35 to 36 weeks) or elective delivery in the absence of labor are becoming increasingly prominent as risk factors.[23] Other risk factors include maternal diabetes and perinatal hypoxia-ischemia. The NICHD Neonatal Research Network reported that 44% of infants between 501 and 1500 g were noted to have RDS, including 71% between 501 and 750 g, 55% between 751 and 1000 g, 37% between 1001 and 1250 g, and 23% between 1251 and 1500 g.[10]

PHARMACOLOGIC ACCELERATION OF PULMONARY MATURATION

In the early 1970s, while studying the effects of steroids on premature labor in lambs, Liggins noticed the lack of RDS and increased survival in preterm animals prenatally exposed to steroids. The effects of various catecholamines as well as aminophylline and thyroid hormone have been studied; however,

the most successful method to induce fetal lung maturation is prenatal corticosteroid administration.[31]

If premature delivery of any infant appears probable or necessary, lung maturity can be hastened pharmacologically. Accelerated lung maturation occurs with physiologic stress levels of corticosteroids, via receptor-mediated induction of specific developmentally regulated proteins, including those associated with surfactant synthesis. Steroids, when administered to the mother at least 24 to 48 hours before delivery, decrease the incidence and severity of RDS. Corticosteroids appear to be most effective before 34 weeks of gestation and when administered at least 24 hours and no longer than 7 days before delivery. Because corticosteroid therapy for less than 24 hours is still associated with significant reductions in neonatal mortality, RDS, and intraventricular hemorrhage (IVH), antenatal steroids should always be considered unless immediate delivery is anticipated.[1] The use of antenatal corticosteroids before 24 weeks' or after 34 weeks' gestation remains controversial.

Less clear are the effects of repeated courses of antenatal corticosteroids on the short- and long-term outcomes of preterm infants. Decreased fetal growth and poorer neurodevelopmental outcomes have been reported in retrospective clinical studies.[4] Therefore, until prospective data are available, caution should be exercised with the widespread use of multicourse therapy.

Concern about the possibility of increased infection in mother or infant appears to be unfounded. Indeed, even when corticosteroids are administered to women with prolonged rupture of membranes, there is no evidence of increased risk of infection, and the neuroprotective effects of corticosteroids are still evident. Maternal steroids may induce an increase in total leukocyte and immature neutrophil counts in the infant, which should be considered if neonatal sepsis is suspected.

There is proven benefit from the combined use of prenatal corticosteroids and postnatal surfactant therapy in preterm infants (see also Surfactant Therapy later in this section). Their effects appear to be additive in improving lung function. Antenatal steroids induce structural maturation of the lung, as evidenced by physiologic and morphometric techniques, that is not secondary to increases in alveolar surfactant pool sizes.[25] These structural changes translate into improved physiologic properties of the lung such as increased lung volume, increased lung compliance, and increased response to exogenous surfactant treatment.

Antenatal corticosteroids appear to reduce the incidence of other comorbidities associated with prematurity including intracranial hemorrhage and necrotizing enterocolitis.[1,30] The beneficial effect on intracranial hemorrhage does not correlate directly with improved pulmonary morbidity and may be secondary to stabilization of cerebral blood flow or a steroid-induced maturation of vascular integrity in the germinal matrix, or both.

In the 1990s, the observation that thyroid hormone could augment lung development and surfactant production in vitro prompted trials of antenatally administered thyrotropin-releasing hormone (TRH). However, these trials failed to demonstrate a benefit and raised concerns for adverse consequences on neurodevelopment, thereby significantly dampening enthusiasm for this therapy.

PATHOPHYSIOLOGY

The lungs of infants who succumb from RDS have a characteristic uniformly ruddy and airless appearance, macroscopically resembling hepatic tissue. On microscopic examination, the striking feature is diffuse atelectasis such that only a few widely dilated alveoli are readily distinguishable (Fig. 44-31). An eosinophilic membrane lines the visible airspaces that usually constitute terminal bronchioles and alveolar ducts. This characteristic membrane (from which the term *hyaline membrane disease* is derived) consists of a fibrinous matrix of materials derived from the blood and contains cellular debris derived from injured epithelium. The recovery phase is characterized by regeneration of alveolar cells, including the type II cells, with a resultant increase in surfactant activity.

The development of RDS begins with impaired or delayed surfactant synthesis and secretion followed by a series of events that may progressively increase the severity of the disease for several days (Fig. 44-32). Surfactant synthesis is a dynamic process that depends on factors such as pH, temperature, and perfusion, and may be compromised by cold stress, hypovolemia, hypoxemia, and acidosis. Other unfavorable factors, such as exposure to high inspired oxygen concentration and the effects of barotrauma and volutrauma from assisted ventilation, can trigger the release of proinflammatory cytokines and chemokines and further damage the alveolar epithelial lining, resulting in reduced surfactant synthesis and function. The leakage of proteins such as fibrin in the intra-alveolar space further aggravates surfactant deficiency by promoting surfactant inactivation. Deficiency of surfactant and the accompanying decrease in lung compliance lead to alveolar hypoventilation and ventilation-perfusion ($\dot{V}/\dot{Q}$) imbalance.

Severe hypoxemia and systemic hypoperfusion result in decreased oxygen delivery with subsequent lactic acidosis secondary to anaerobic metabolism. Hypoxemia and acidosis also result in pulmonary hypoperfusion secondary to pulmonary vasoconstriction, and the result is a further aggravation of hypoxemia due to right-to-left shunting at the level of the ductus arteriosus and foramen ovale and within the lung itself.

Chronic neonatal lung disease

Figure 44–32. Schematic representation of the complex series of acute and chronic events that lead to neonatal respiratory distress syndrome and the accompanying lung injury secondary to therapeutic intervention in these infants.

The relative roles of surfactant deficiency and pulmonary hypoperfusion in the overall clinical picture of RDS vary somewhat with each patient. The natural history of RDS is now almost invariably altered by a combination of exogenous surfactant therapy and assisted ventilation.

Heritability of Respiratory Distress Syndrome

A genetic contribution to the risk of RDS has been suggested in twin studies where the concordance of RDS in monozygotic twins is greater than that of dizygotic twins and with isolated reports of recurrence in families.[27,33] With the application of molecular techniques, the contribution of genetic variations (polymorphisms, mutations) to the pathogenesis of respiratory disorders in newborns has rapidly emerged.[7]

Mutations in genes encoding surfactant protein-B (*SFTPB*), surfactant protein-C (*SFTPC*), and the adenosine triphosphate (ATP)-binding cassette subfamily A, member 3 (*ABCA3*) represent rare monogenic causes of RDS.[6,18] Inherited surfactant protein-B (SP-B) deficiency is a recessive disorder that presents as severe respiratory failure in the immediate newborn period and is unresponsive to standard intensive care interventions. With a disease frequency of approximately 1 per million live births, the absence of SP-B, the presence of an incompletely processed proSP-C, and a generalized disruption of surfactant metabolism cause surfactant dysfunction and the clinical syndrome. Dominant mutations in *SFTPC* typically result in interstitial lung disease in infants older than 1 month of age, although an “RDS-like” presentation has been described. The accumulation of misfolded proSP-C within cellular secretory pathways results in activation of cell stress responses and apoptosis and impaired surfactant function. The frequency of disease due to recessive mutations in *ABCA3* in the population is unknown although initial studies suggest that *ABCA3* deficiency may be the most common of these disorders of surfactant homeostasis. Over 150 mutations in *ABCA3* have been identified in association with lethal RDS in newborns and with chronic respiratory insufficiency in children. Even though the exact role of *ABCA3* in surfactant metabolism remains unknown, data from humans and mice suggest that *ABCA3* mediates phosphatidylcholine (PC) and phosphatidylglycerol (PG) transport into lamellar bodies, and thus dysfunction of phospholipid transport into the lamellar body leads to reduced surfactant function.[11,15] One variant, a substitution of valine for glutamic acid in codon 292 (E292V) has been found in approximately 0.4% of the general population and in 4% of a cohort of preterm and term infants with RDS, suggesting that this variant may be a genetic modifier for the risk or severity of respiratory disease in susceptible individuals.[14]

Large-scale genotyping and resequencing efforts have failed to identify an unequivocal contribution of rare or common variants in the surfactant protein-B or -C genes to RDS in newborns, suggesting that if these genes play a role in RDS, it is likely to be through interactions with variants in other lung-associated genes.[17] High throughput resequencing methods and novel statistical approaches will be necessary to detect these interactions between rare and common variants in pathways that influence lung development and respiratory transition in the newborn period.[48]

CLINICAL FEATURES

The classic clinical presentation of RDS includes grunting respirations, retractions, nasal flaring, cyanosis, and increased oxygen requirement, together with diagnostic radiographic findings and onset of symptoms shortly after birth. The respiratory rate is usually regular and increased well above the normal range of 30 to 60 breaths per minute. These patients usually show progression of symptoms and require supplemental oxygen. The presence of apneic episodes at this early stage is an ominous sign that could reflect thermal instability or sepsis but more often is a sign of hypoxemia and respiratory failure. This characteristic picture is modified in many infants with low birthweight as a result of the early administration of exogenous surfactant and immediate assisted ventilation.

Retractions are prominent and are the result of the compliant rib cage collapse on inspiration as the infant generates high intrathoracic pressures to expand the poorly compliant lungs. The typical expiratory grunt is an early feature of the clinical course and may subsequently disappear. It is believed to result from partial closure of the glottis during expiration and in this way acts as a means of trapping alveolar air and maintaining functional residual capacity (FRC). Although these signs are characteristic for neonatal RDS, they can result from a wide variety of nonpulmonary causes, such as hypothermia, hypoglycemia, anemia, or polycythemia; furthermore, such nonpulmonary conditions can complicate the clinical course of RDS.

Cyanosis is a consequence of right-to-left shunting in RDS and is typically relieved by administering a higher concentration of oxygen and ventilatory support. Impaired cardiac output resulting from respiratory effort that is asynchronous with the ventilator may further impede oxygen delivery and lead to poor peripheral perfusion or cyanosis. The consistency of the arterial wave form with invasive blood pressure monitoring or the pulse signal with oxygen saturation monitoring can provide information about the effectiveness of cardiac output. Acrocyanosis of the hands and feet is a common finding in normal infants and should not be confused with central cyanosis, which always must be investigated and treated. Peripheral edema, often present in RDS, is of no particular prognostic significance unless it is associated with hydrops fetalis.

During auscultation of the chest, breath sounds are widely transmitted and cannot be relied upon to reflect pathologic conditions. Nonhomogeneous aeration plus elevated endogenously or exogenously generated intrathoracic pressures can cause pulmonary air leaks. Thus unilaterally decreased breath sounds (with mediastinal shift to the opposite side) or bilaterally decreased air entry could indicate pneumothorax, and immediate transillumination must be performed. Chest radiography is also needed to confirm endotracheal tube placement if air entry sounds asymmetric. The murmur of a PDA is most often audible during the recovery phase of RDS, when pulmonary vascular resistance has fallen below systemic levels and there is left-to-right shunting. Distant, muffled heart sounds should alert one to the possibility of pneumopericardium. Percussion of the chest is of no diagnostic value in preterm infants.

A constant feature of RDS is the early onset of clinical signs of the disease. Most infants present with signs and symptoms either in the delivery room or within the first 6 hours after birth. Inadequate observation can lead to the impression of a symptom-free period of several hours. The uncomplicated clinical course is characterized by a progressive worsening of symptoms with a peak severity by days 2 to 3 and onset of recovery by 72 hours. Surfactant therapy often greatly shortens this course. When the disease process is severe enough to require assisted ventilation or is complicated by the development of air leaks, significant shunting through a PDA, or early signs of BPD, recovery can be delayed for days, weeks, or months (see Fig. 44-32). In the most affected patients, the transition from the recovery phase of RDS to BPD is clinically imperceptible.

RADIOGRAPHIC FINDINGS

See also Chapter 37.

The diagnosis of RDS is based on a combination of the previously described clinical features, evidence of prematurity, exclusion of other causes of respiratory distress, and characteristic radiographic appearance. The typical radiographic features consist of a diffuse reticulogranular pattern, giving the classic ground-glass appearance, in both lung fields with superimposed air bronchograms (Fig. 44-33). Although the radiologic appearance of RDS is typically symmetric and homogeneous, asymmetry has also been described, especially if surfactant therapy has been administered preferentially to one side.

The reticulogranular pattern is primarily caused by alveolar atelectasis, although there may be some component of pulmonary edema. The prominent air bronchograms represent aerated bronchioles superimposed on a background of nonaerated alveoli. An area of localized air bronchograms may be normal in the left lower lobe overlying the cardiac silhouette, but in RDS they are widely distributed, particularly in the upper lobes. In the most severe cases, a complete whiteout of the lungs can be observed with total loss of heart borders. Heart size is typically normal or slightly increased. Cardiomegaly may herald the development of congestive cardiac failure from a PDA. After the administration of exogenous surfactant therapy, the chest radiograph usually shows improved aeration of the lungs bilaterally; however, asymmetric clearing of the lungs may occur.

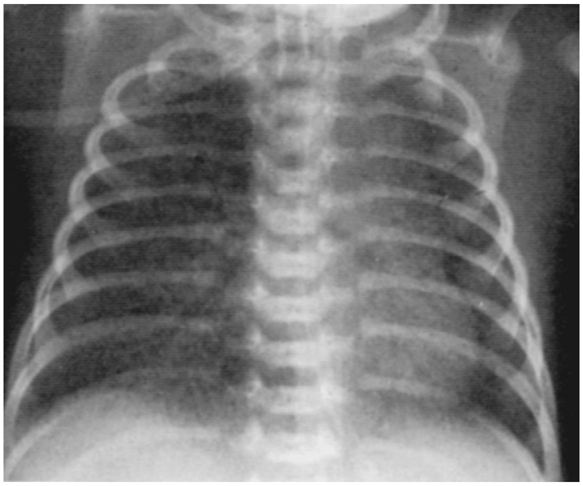

Figure 44–33. Typical radiographic appearance of respiratory distress syndrome with reticulogranular infiltrate and air bronchograms.

The radiographic appearance of RDS, typical or atypical, cannot be reliably differentiated from that of neonatal pneumonia, which is most commonly caused by group B streptococci. This problem has been the major reason for the widespread use of antibiotics in the initial management of infants with RDS. Infants with RDS reportedly have a larger thymic silhouette than infants of comparable size without RDS. This supports the theory that patients with RDS have had reduced exposure to endogenous corticosteroids during fetal life.

Echocardiographic evaluation of infants with RDS may be of value in the diagnosis of a PDA to quantitate elevations in pulmonary artery pressure, to assess cardiac function, and to exclude congenital heart disease (e.g., obstructed total anomalous pulmonary venous return).

TREATMENT

Therapy for RDS includes careful application of general supportive measures supplemented by surfactant therapy and specific means of controlling and assisting ventilation. Close and detailed supervision of small infants requires a dedicated, trained staff experienced in problems specific to the newborn and skillful in the unique technical procedures involved, such as assessment of neonatal blood gases.

Positive Pressure Ventilation

See Part 4.

Delivery of distending pressure to maintain airway and alveolar expansion through invasive and noninvasive means is the mainstay of treatment for RDS. The most common approaches of invasive mechanical ventilation via an endotracheal tube use a time-cycled, pressure-limited mode or volume-controlled mode with synchronized ventilated breaths. Alternatively, high-frequency jet ventilation or high-frequency oscillatory ventilation is used both as a primary means of ventilation as well as rescue when conventional ventilation has failed. Increasing enthusiasm for nasal continuous positive airway pressure (CPAP) to deliver positive pressure has demonstrated that many premature infants can be successfully managed without intubation or with intubation only for surfactant administration.[32,44]

Surfactant Therapy

No intervention in the past 20 years has had more impact on the care of newborns with RDS than surfactant replacement therapy, which was first introduced in 1990. A thorough history of the development of surfactant replacement therapy can be found in reference 16. The discovery that surfactant deficiency was key in the pathophysiology of RDS led several investigators to administer artificial aerosolized phospholipids to infants with RDS. In these early studies, only limited therapeutic success was encountered. In contrast, animal models in which natural surfactant compounds were used yielded more promising results.

Because intact lung preparations were not available in Japan, Fujiwara and coworkers developed a mixture of both natural and synthetic surface-active lipids for use in humans.[12] Such a mixture might also afford alveolar stability with less potential risk for a reaction to foreign protein than would be the case with exclusively natural surfactant. When administered to an initial group of 10 preterm infants with severe RDS who were not improving despite artificial ventilation, a single 10-mL dose of surfactant instilled into the endotracheal tube resulted in a dramatic decrease in inspired oxygen and ventilator pressures. None of the infants in this uncontrolled series subsequently succumbed from RDS. Recovery, however, was complicated by clinical evidence of a PDA in nine of the infants, possibly the result of a prompt fall in pulmonary vascular resistance with the resultant left-to-right shunting after surfactant therapy.

Multiple studies have employed various combinations of prevention (delivery room administration) and rescue (administration for established RDS) protocols using synthetic and mixed natural-synthetic preparations.[24,41,42] Synthetic-only preparations used protein-free synthetic phospholipid products which contain alcohol to act as a spreading agent for dipalmitoyl phosphatidylcholine at the air-fluid-alveolar interface.[35] The mixed-surfactant preparations contain extracts of calf lung lavage or minced bovine or porcine lung. Direct comparison between synthetic and natural preparations has revealed a more rapid physiologic response after natural (protein-containing) preparations as manifested by the ability to lower inspired oxygen and ventilator pressures.[41] Comparison of natural surfactants has shown modest differences in oxygenation during the first few hours after treatment, without a significant effect on morbidity or mortality. Despite differences in their chemical composition and manufacturing methods, formulations currently approved by the U.S. Food and Drug Administration demonstrate comparable clinical efficacy.

All regimens of surfactant therapy appear to decrease the incidence of air leaks and improve oxygenation of ventilated preterm infants. More strikingly, mortality from RDS, and even overall mortality of ventilated preterm infants, is significantly reduced, especially when multidose surfactant therapy is used for these infants. Early selective surfactant administration (within 2 hours after birth) given to infants with RDS requiring assisted ventilation leads to decreased risk of pneumothorax and pulmonary interstitial emphysema and a decreased risk of neonatal mortality and chronic lung disease compared with delaying treatment until RDS is well established. Furthermore, this strategy does seem to reduce the need for subsequent retreatment and the requirement for supplemental oxygen and mechanical ventilation.[34,42] However, it is unclear whether a preventive dose administered endotracheally in the delivery room (prophylactic) has any advantage over treatment given after the patient has been resuscitated and stabilized (early treatment).[22] Such preventive therapy is only relevant for very immature infants who are most likely to develop significant lung disease, but this therapy is potentially prone to administration errors related to suboptimal endotracheal tube placement or the unnecessary treatment of many babies who were not destined to develop RDS. Furthermore the SUPPORT trial demonstrated that 17% of extremely low birthweight infants may never need intubation.[44a]

The dramatic improvement in oxygenation is not accompanied by an immediate improvement in $\mathrm{Pa{CO}_2}$ if ventilator settings remain unchanged more than 30 minutes after surfactant therapy. These data strongly suggest that enhanced matching of ventilation and perfusion is the primary mechanism whereby surfactant dramatically improves $\mathrm{Pa{O}_2}$ in preterm infants with RDS. Consistent with the failure of $\mathrm{Pa{CO}_2}$

to improve rapidly are observations that lung compliance does not improve rapidly after surfactant therapy. Dramatic improvement in oxygenation after surfactant therapy does correlate with an increase in lung volume and resultant stabilization of FRC. This improvement occurs despite the failure of lung compliance to increase rapidly and suggests that surfactant therapy might induce regional overdistention of alveoli. However, if lung compliance is measured on spontaneous rather than ventilator breaths, or if ventilator pressures are promptly lowered in response to the increase in $\mathrm{PaO_2}$ induced by surfactant therapy, then an increase in compliance in response to surfactant can be seen.[8] In contrast with the impressive improvement in mortality, the incidence of BPD, IVH, sepsis, and symptomatic PDA appears unaltered in most studies.[24] Of particular interest is the failure of surfactant therapy to significantly reduce the incidence of BPD. Although individual studies have shown a decreased incidence of BPD, these results have not been substantiated by meta-analysis of large randomized trials. This could be a consequence of the enhanced survival caused by surfactant administration to infants who are very preterm. Furthermore, many infants who are preterm develop BPD without antecedent RDS.

Data from the early trials suggested slightly higher pulmonary hemorrhage rates in association with surfactant therapy in the smallest and most immature infants. However, these findings have not been consistent throughout the literature, and controversy still exists. Pulmonary hemorrhage has been reported in up to 6% of preterm infants treated with exogenous surfactant and typically occurs in the first 72 hours of life.[13] Generally, an acute deterioration in oxygenation and ventilation accompanied by variable degrees of cardiovascular compromise constitute the typical clinical findings. One of the major hurdles encountered in defining the magnitude of the problem has been the lack of precise diagnostic criteria. In surfactant-treated infants, there tends to be extensive intra-alveolar hemorrhage, in contrast to infants not exposed to surfactant therapy, in whom hemorrhages occur as interstitial hemorrhage and localized hematomas. The improvement in lung compliance after surfactant therapy probably promotes an increase in left-to-right shunt through the PDA. The increase in pulmonary blood flow results in pulmonary congestion and elevated capillary pressure. Stress failure of alveolar capillaries and their supporting epithelial tissues leads to intra-alveolar hemorrhagic pulmonary edema. In the large randomized, controlled trial of prophylactic indomethacin for prevention of IVH, despite a significant reduction in PDA in the treated group, the incidence of pulmonary hemorrhage did not change (Box 44-3).[37] A follow-up study of infants who developed pulmonary hemorrhage after surfactant administration showed no difference in the incidence of BPD, necrotizing enterocolitis, or intracranial hemorrhage. Furthermore, the neurodevelopmental outcome assessed by the Bayley Mental Developmental Index at 20 months of age was also similar.[45] Thus, although the role of PDA in the pathogenesis of pulmonary hemorrhage has not been conclusively demonstrated, a PDA is a frequent contributing factor.

Some infants do not exhibit the anticipated favorable response to surfactant therapy. The need for a high oxygen concentration and ventilatory pressures during the early stages of RDS has been identified as a risk factor for an inadequate response. Animal studies have shown that even a few large tidal volume breaths in a surfactant-deficient lung are associated with alveolar accumulation of protein-rich edema fluid and decreased response to surfactant treatment.[21] Thus, it is unclear if lack of response is secondary to the initial severity of the disease or to the damage induced by short periods of aggressive ventilation prior to surfactant replacement. Furthermore, reactive oxygen species in preterm infants with poorly developed antioxidant defenses (i.e., superoxide dismutase, catalase, and reduced glutathione) may inactivate endogenous and exogenous surfactants. Finally, intrauterine inflammation or genetically determined factors may disrupt lung development or endogenous surfactant metabolism thereby influencing response to surfactant therapy.

Data from large numbers of infants in the United States and Europe indicate no adverse effects on physical growth, respiratory symptoms, or neurodevelopmental outcome. In a systematic review of randomized, controlled trials, surfactant treatment was associated with a reduction in the combined outcomes of death or severe disability at 1 year of age.[40] Furthermore, this improvement in mortality and morbidity induced by surfactant therapy is accompanied by significant cost savings.[38]

BOX 44–3 Surfactant Therapy for Respiratory Distress Syndrome

RESOLVED

- Improved mortality from respiratory distress syndrome (RDS)
- Greatest benefit when antenatal corticosteroids are also employed
- Exogenous surfactant does not inhibit endogenous surfactant synthesis
- Retreatment may be required in severe RDS
- Major component for lowering surface tension: phosphatidylcholine
- Endotracheal intubation required for administration of fluid suspension
- Improvement in oxygenation, functional residual capacity, and lung compliance
- Protein-containing preparations show a faster therapeutic response
- Decrease in incidence of air leaks
- Prophylactic or early use beneficial in infants with extremely low birthweight (<29 weeks' gestation)
- Efficacy of surfactant therapy, early extubation, nasal continuous positive airway pressure strategy

UNRESOLVED

- Factors predicting likelihood of success of an initial CPAP-based strategy
- Optimal ventilatory strategy to maximize surfactant response
- Effect on incidence and severity of bronchopulmonary dysplasia
- Role of surfactant proteins as modulator of the immune system and inflammatory response
- Role for recombinant surfactant protein-based preparations

Despite the efficacy of currently available surfactant preparations, attempts to enhance these preparations continue. Although no adverse immunologic consequences of foreign tissue protein administration have been reported in the recipients of natural surfactant therapy, concerns for transmitted disease prompt the desire to develop synthetic, non-animal based products. Preparations that contain synthetic peptides that mimic the biophysical properties of SP-B or SP-C have been studied in newborns (SP-B) and adults (SP-C) but have not found their way into general use.[26,43] SP-A and SP-D, while not essential for surface-lowering activity, could play a significant role in the lung's innate immune response and modulation of inflammation. It is not yet known whether the use of purified SP-A or recombinant SP-D has a therapeutic role in neonatal lung disease. The combination of a new generation of surfactants along with a gentler ventilatory approach could hold the key to optimal pulmonary outcomes in the future.

Inhaled Nitric Oxide Therapy

Inhaled nitric oxide, currently approved for treatment of hypoxic respiratory failure in near-term and full-term infants, has been proposed as a potential intervention in premature infants at risk for development of BPD. Although trials have suggested short-term benefits in improved survival without BPD and decreased use of bronchodilators and steroids in the first year, the impact on longer-term neurodevelopmental outcome is unknown. Further evaluation of the short-term and long-term effects of this intervention is needed, especially as several trials have failed to show benefit in preterm infants (See Part 8).[19]

Assessment of Blood Gas Status

See also Part 2.

The ability to accurately monitor gas exchange is essential in all cases of neonatal respiratory disease. In its most basic form this involves intermittent arterial sampling, usually via an indwelling umbilical arterial catheter or, less commonly, a peripheral (e.g., radial) arterial line. Infants with acute respiratory distress requiring a significantly increased inspired oxygen concentration or assisted ventilation should have blood gases sampled every 4 hours or more often as their clinical condition dictates.

In infants with RDS, partial pressure of arterial oxygen ($Pa{O_2}$) is customarily maintained between 50 and 80 mm Hg, $Pa{CO_2}$ in the 40 to 55 mm Hg range, and pH at least 7.25, although in the most immature infants, these ranges have been relaxed to minimize oxygen supplementation and the degree of ventilatory support in an effort to decrease oxygen- and ventilation-associated morbidity.[2,23] Analysis of continuous in-line arterial blood gases and electrolytes has been introduced in neonatal intensive care units. This promising technology offers advantages over intermittent sampling: less handling of the critically ill patient, fewer breaks in the line that could introduce infection, and continuous evaluation of therapeutic maneuvers.[49] In conjunction with continuous noninvasive monitoring of oxygen saturation, it is possible to rapidly identify clinical deterioration, expedite weaning, and minimize morbidity from oxygen toxicity or hypocarbia. Moreover, the need for blood sampling is substantially decreased, which can decrease the incidence of iatrogenic anemia and the need for blood transfusions.

One should bear in mind that a normal arterial oxygen tension or saturation does not ensure adequate tissue oxygen delivery, because oxygen delivery is dependent on cardiac output and oxygen content of the blood. Therefore, interpretation of gas exchange should always be correlated with a thorough clinical assessment.

ARTERIAL SAMPLING

Umbilical catheterization should be performed by an experienced operator and under strict surgical aseptic technique. Once the umbilical arteries have been identified by their anatomic characteristics, one of the vessels is dilated with the use of an iris forceps. The catheter is then gently advanced to a predetermined length that will place its tip at a high (T6-T8) or at a low (L3-L4) position. Several methods have been developed to estimate the length of catheter to be inserted to achieve proper placement; however, radiologic confirmation of catheter position is still imperative.

Although umbilical artery catheters still form the basic means of arterial sampling in infants with RDS, the list of catheter-related complications is formidable. The most common visible problem from an umbilical or radial line is blanching or cyanosis of part or all of a distal extremity or the buttock area, resulting either from vasospasm or a thrombotic or embolic incident. This complication may be reduced in the case of an umbilical catheter by high placement, with the catheter tip at the level of T7 or T8 as opposed to lower placement at L3 or L4 just above the aortic bifurcation.

Tyson and associates observed thromboatheromatous complications resulting from umbilical artery catheters in 33 of 56 neonates at autopsy.[46] Hypertension can result if a renal artery is involved. A rare complication of indwelling arterial umbilical catheters is aneurysmal dilation with dissection of the abdominal aorta, which can be diagnosed by careful ultrasound examination. Passage of a catheter beyond the origin of the superior mesenteric artery might increase the risk of necrotizing enterocolitis. Retrograde blood flow into the proximal aorta can occur during flushing of radial and umbilical artery lines and result in transient blood pressure elevation; therefore, routine flushing should be performed with a small volume over a period of several seconds.

Small amounts of heparin added to the continuous infusion appear to reduce the risk of arterial thrombi. Use of siliconized catheters is associated with decreased thrombogenicity. Catheter-associated thrombosis may be further reduced by limiting the number of days these catheters remain in place. All these complications illustrate the importance of applying rigid criteria for the insertion and removal of indwelling arterial catheters and the need for less hazardous methods of monitoring blood gases.

If a peripheral arterial catheter is to be used, an Allen test should be performed prior to the insertion of a radial artery line to establish the presence of adequate collateral circulation to the fingers.

NONINVASIVE MONITORING: PULSE OXIMETRY

Risk of infection and other complications have prompted early umbilical line removal and increased the reliance on noninvasive methods for measuring gas exchange. Pulse oximetry is a well-established technique for indirectly determining oxygenation in a noninvasive and continuous manner. For infants with mild respiratory distress, pulse oximetry is extremely valuable and could make an umbilical arterial catheter unnecessary, as long as intermittent assessments of pH and P_{CO_2} are made. Generally this is not the case in infants with moderate or severe respiratory disease in whom noninvasive measurement remains an important adjunct rather than a substitute for arterial blood gas sampling.

Continuous noninvasive measurement of arterial hemoglobin oxygen saturation (pulse oximetry) has gained widespread acceptance. Pulse oximetry typically employs a microprocessor-based pulse oximeter consisting of a light-emitting probe attached to a distal extremity of the infant. Oxygen saturation is computed from the light absorption characteristics of the pulsatile flow (containing both oxygenated and nonoxygenated hemoglobin) as it passes beneath the probe. The monitor readings closely correlate with saturation measurements obtained from arterial samples (see also Part 2).

The major disadvantage of pulse oximetry is that changes in saturation are small on the flat portion of the hemoglobin dissociation curve at Pa_{O_2} values greater than about 60 mm Hg (depending on the fetal hemoglobin content and other factors affecting position of the hemoglobin dissociation curve). This is not a substantial problem in infants with BPD when oxygen saturation is generally maintained in the high 80s to mid 90s, and these infants are unlikely to be at risk for hyperoxemia. On the other hand, significant decreases in severe forms of retinopathy of prematurity have been seen when oxygen saturation limits are constrained between 85% and 92%; thus oxygen supplementation is more restricted.[20] However, significant variability in even resting oxygen saturations in some infants provides a significant challenge to administer the appropriate amount of oxygen to remain within these constraints.

Pulse oximeters are technically easy to use, do not require calibration or heating of the skin, and provide immediate data on arterial oxygenation. However, this ease of use can allow misinterpretation of potentially erroneous measurements.[36] Placement must not be associated with excess pressure, and peripheral perfusion must be adequate, although pulse oximeters are less dependent on peripheral perfusion than the previously widely used transcutaneous Pa_{O_2} probes. Pulse oximeters are quite sensitive to sudden changes in background signal such as those due to body movements. It is therefore important to ensure that the pulsatile waveforms, from which oxygen saturation is derived, are not distorted. This is typically done by comparing pulse rate from the oximeter with heart rate obtained from a cardiorespiratory monitor; these values should be identical. Newer signal extraction technology has significantly improved the accuracy and reliability of pulse oximetry measurements.

A major effect of pulse oximetry has been the ability to rapidly optimize respiratory care and drastically reduce the time required to determine optimum inspired oxygen concentrations, levels of CPAP, and respirator settings. Other benefits include the ability to assess responses to all procedures, including surfactant instillation, as well as excessive handling. Complications such as pneumothorax, endotracheal tube dislodgement, disconnection from oxygen supply, and respirator malfunction are rapidly recognized so that immediate corrective treatment can be initiated. Episodes of hypoxemia or desaturation can occur spontaneously or accompany feeds and have complex etiologies, as discussed elsewhere in this text. Noninvasive monitoring of oxygenation allows such episodes to be identified and their relationship to apnea and bradycardia recorded.

NONINVASIVE CARBON DIOXIDE MONITORING

Although not used as universally as pulse oximetry, noninvasive methods for monitoring carbon dioxide levels can also provide an important adjunct to blood gas monitoring. Capnography has become the standard of care in resuscitation situations for accurately and rapidly demonstrating that the endotracheal tube is in the airway (see also Chapter 26, Part 2). End-tidal CO_2 monitoring, though routinely used during anesthesia, is useful for following trends, but is not always reliable in very low birthweight infants. Transcutaneous P_{CO_2} monitoring is also useful for monitoring trends, especially when trying to optimize the ventilatory settings when initiating conventional or high-frequency ventilation. The association of Pa_{CO_2} levels of less than 30 mm Hg with periventricular leukomalacia in premature newborns demonstrates the need for careful CO_2 monitoring.[39]

General Measures

THERMOREGULATION

Infants with respiratory difficulty require an optimal thermal environment to minimize oxygen consumption and oxygen requirements. Infants who are hypoxic lose the ability to increase metabolic rate when they are cold stressed, and a fall in body temperature may be noted. Thus, meticulous attention must be paid to the temperature and humidity of the infant's environment and inspired air so that the appropriate neutral thermal environment can be maintained.

FLUID, ELECTROLYTES, AND NUTRITION

See also Chapters 35 and 36.

The importance of nutritional support for infants with RDS cannot be overemphasized. The ability to supply an adequate caloric intake to the critically ill infant receiving respiratory assistance is facilitated by intravenous glucose, amino acid, and lipid solutions. Premature infants receiving as little as 60 cal/kg per day, with 10% of the calories provided as protein, could remain in positive nitrogen balance. It is now common practice to start administration of an amino acid–glucose solution by the first day of life, especially for infants weighing less than 1000 g and receiving mechanical ventilation. Small-volume gavage feedings of breast milk or formula should be initiated as early as feasible.

Fluid balance must be closely watched because overenthusiastic attention to calories can cause fluid overload and perhaps contribute to the development of a clinically significant PDA. Maintenance fluid requirements usually begin at 60 to 80 mL/kg per day as a 10% dextrose solution and increase gradually to 120 mL/kg per day by the fifth day of life. However, these fluid requirements are greatly modified by many additional factors, particularly the high insensible water loss experienced by many infants with very low birthweight under radiant warmers or phototherapy and the limited concentrating ability of immature kidneys (see Chapter 36). In a prospective study using sequential analysis, Bell and associates showed that the risk of a PDA with congestive heart failure was greater in infants receiving a high-fluid volume regimen (169 ± 20 mL/kg per day) than in those on a low-volume regimen (122 ± 14 mL/kg per day). In the high-volume group, 35 (41%) of 85 developed murmurs consistent with a PDA, and 11 of these were associated with congestive heart failure. In contrast, only 9 (11%) of the 85 infants in the low-volume group had a PDA murmur, and congestive heart failure developed in 2. More cases of necrotizing enterocolitis also were observed in the high-volume group.[5] These results, together with other data, indicate that limitation of fluid intake could possibly reduce the risk of PDA, necrotizing enterocolitis, and even BPD, although routine or prophylactic diuretic therapy cannot be recommended. Fluid therapy in infants with RDS is thus a critical aspect of care.

In infants with extremely low birthweight, especially during the first few days of life, free water depletion due to high insensible water losses could lead to hypernatremic dehydration. Later, usually after the first week of life, the renal inability to conserve salt, a low sodium intake, overzealous use of diuretics, or the osmotic diuresis associated with hyperglycemia can precipitate hyponatremia, particularly in infants weighing less than 1000 g. Maintenance of sodium balance usually is achieved by administering 2 to 4 mEq/kg per day of sodium, commencing at 48 to 72 hours, and closely monitoring serum sodium levels. Potassium balance is accomplished by adding 1 to 2 mEq/kg per day to the intravenous infusion from the second day of life, as long as normal renal function and diuresis are present. In the more immature infant, nonoliguric hyperkalemia might be present secondary to a shift of intracellular potassium to the extracellular space due to an immature Na^+, K^+-ATPase pump. Thus serum electrolytes should be monitored sequentially to determine proper adjustments of fluid therapy.

ACID-BASE THERAPY

A change in acid-base balance should prompt a rapid determination of the type of imbalance, respiratory or metabolic, and a thorough evaluation of the cause. Acidosis, respiratory or metabolic, especially when coupled with hypoxia, can cause pulmonary arterial vasoconstriction and ventilation-perfusion abnormalities, decreased cardiac output, or both. Metabolic acidosis is most often encountered when the infant was depressed at birth and required resuscitation. A subsequent metabolic acidosis out of proportion to the degree of respiratory distress might signify hypoperfusion, sepsis, or an IVH. Metabolic acidosis occurring at any time typically improves with sodium bicarbonate administration, as long as there are no signs of respiratory failure that might hinder elimination of carbon dioxide. Sodium bicarbonate is hypertonic and thus should be administered slowly and judiciously. Rapid infusions may increase blood osmolality and predispose to intracranial hemorrhage or hepatic necrosis (if administered through an umbilical venous catheter with the tip in the liver).

Respiratory acidosis requires assisted ventilation. Administration of sodium bicarbonate to infants with respiratory acidosis is not indicated and could further increase the P_{CO_2}. For infants in respiratory acidosis, alkali therapy should be withheld until some form of assisted ventilation has been initiated. If this fails to improve oxygenation and raise the pH, sodium bicarbonate may be administered while continuing with assisted ventilation and always attempting to determine the cause of the acidosis. In recent years, the administration of sodium bicarbonate has been increasingly challenged, and its role in treating metabolic acidosis in neonates is very limited.

CARDIOVASCULAR MANAGEMENT

Comprehensive management of patients with RDS includes a close evaluation and monitoring of the cardiovascular system. An in-depth understanding of the physical and physiologic interactions between the cardiovascular and pulmonary systems in the mechanically ventilated patient is paramount. For example, after surfactant administration, with the improvement in the mechanical properties of the lungs, an unrecognized overdistention of the lungs by excessive mechanical ventilation support can decrease systemic venous return to the heart that results in a decrease in cardiac output. Radiographically, a typical squeezed-heart silhouette and flattened diaphragm are found. A thorough clinical evaluation should include sequential assessment of vital signs, peripheral pulses, capillary refill, and urine output as surrogate markers of adequate cardiac output.

Myocardial dysfunction secondary to birth asphyxia may be present and could lead to decreased peripheral perfusion with lactic acidemia and metabolic acidosis. Systemic hypotension is common in the early stages of RDS; thus continuous monitoring of systemic blood pressure by means of an indwelling arterial catheter is of utmost importance in the moderately to severely ill infant. Noninvasive intermittent monitoring of systemic blood pressure should be reserved for the mildly affected neonate. Judicious use of crystalloids for intravascular expansion and vasopressor support are often indicated. In patients with persistent hypotension not responsive to fluid therapy or catecholamines, serum cortisol levels should be measured and treatment with stress doses of hydrocortisone should be considered.

Failure of the ductus arteriosus to close is a common complication in infants with RDS and has been linked to the development of necrotizing enterocolitis and BPD. Clinically, the presence of a PDA is heralded by a widened pulse pressure, an active precordium, and bounding peripheral pulses. A heart murmur on the left subclavicular area and the back is often present. On the chest radiograph, cardiomegaly might signal the presence of a hemodynamically significant PDA with congestive heart failure. With clinical suspicion, a confirmatory echocardiogram, which should demonstrate evidence of pulmonary overcirculation, such as left atrial enlargement, is usually obtained before proceeding with the pharmacologic closure of the ductus arteriosus with a prostaglandin synthesis inhibitor such as indomethacin or ibuprofen.[47] Fluid restriction, vasopressors, and a loop diuretic (e.g., furosemide) may be indicated for the medical management of a hemodynamically significant PDA with congestive heart failure.

ANTIBIOTICS

Neonatal pneumonia (most commonly caused by group B streptococci) can be indistinguishable from RDS both clinically and radiographically. Such infection usually is acquired around the time of delivery either through ascending infection or passage through a colonized genital tract. The potentially fulminant course of neonatal pneumonia, especially in preterm infants, and the difficulty in distinguishing it from RDS have led to the recommendation that all infants with significant respiratory distress receive antibiotics after appropriate cultures.

Prenatal features suggestive of neonatal infection include maternal fever, prolonged rupture of membranes, and clinical evidence of chorioamnionitis. The suspicion for bacterial infection is raised by a history of maternal genital colonization with group B streptococci, especially in an inadequately treated mother. In recent years pneumonia or sepsis from gram negative organisms, such as E. Coli, may pose an even greater risk.

In the newborn, persistent hypotension, metabolic acidosis, early onset of apnea, neutropenia, and neutrophilia accompanied by an increase in immature cells (left shift) are clinical findings suggestive of systemic infection. Nonetheless, the absence of these features does not exclude the diagnosis of pneumonia. A penicillin combined with an aminoglycoside is the antibiotic regimen of choice and should be discontinued after 48 hours if cultures are negative. Appropriate gram negative organism coverage must be a consideration.

BLOOD TRANSFUSION

In the acutely ill newborn with RDS, mild anemia, which is usually well tolerated by asymptomatic preterm infants, can significantly decrease oxygen content of blood and tissue oxygen delivery. During the first few days of life, anemia is usually the result of excessive blood extraction for laboratory determinations. In-line blood gas and chemistry analyzers and microsampling techniques have significantly decreased the volume of blood required for testing. This decrease should translate into a decrease in blood loss and transfusion requirements.

It is customary to maintain a venous hematocrit of at least 35% to 40% during the acute phase of RDS to support an adequate oxygen-carrying capacity because, in the presence of anemia, most infants do not manifest any signs of impaired oxygen-carrying capacity. Thus the potential risks of blood replacement, including transmission of infectious agents, blood group antigen exposure, or rarely iron overload, should be carefully considered.

Administration of recombinant human erythropoietin over the first 6 weeks of life for preventing anemia in infants with extremely low birthweight during the acute phase of RDS remains controversial.[28]

Despite substantial improvements in the treatment of RDS, prevention of premature birth is still an ultimate goal and will have significant impact on the prevention of RDS. In the meantime, understanding the interactions of the intrauterine environment and genetic determinants of lung development to the pathogenesis of RDS is essential to develop mechanism-specific interventions.

PART 4

Assisted Ventilation and Its Complications

Steven M. Donn and Sunil K. Sinha

Mechanical ventilation has been used to treat neonatal respiratory failure for nearly a half century. The earliest applications began as modifications of adult ventilators, treating babies of modest size and prematurity by today's standards.[21] Most devices were time-cycled, pressure-limited ventilators. Landmark advances in respiratory care occurred in the 1970s. Antenatal corticosteroids were shown to enhance fetal lung maturity, and transcutaneous oxygen monitoring taught much about the vulnerability of the preterm infant. The 1980s brought pulse oximetry and high-frequency ventilation (HFV), which greatly expanded the therapeutic armamentarium. The surfactant replacement era began in the 1990s and was accompanied contemporaneously by patient-triggered ventilation, real-time pulmonary graphics, and a host of pharmacologic agents. Finally, in the new millennium, the microprocessor was incorporated into neonatal ventilators to greatly expand capabilities, monitoring, safety, and efficacy. This technological revolution has extended survival to infants born extremely prematurely as well as those with severe pulmonary disease that was heretofore lethal.

Mechanical ventilation can now be provided in many permutations. Clinicians can alter target variables, waveforms, cycling mechanisms, and modes simply by adjusting a dial. This has led to the development of disease-specific strategies to deal with the wide spectrum of neonatal respiratory failure. Similar to the rapidity of change in the computer industry, advances have been rapid and are often introduced into clinical practice without much of an evidence base, causing further confusion and consternation. This chapter reviews the classification and principles of both noninvasive ventilation and mechanical ventilation, with an emphasis on nomenclature and terminology.

CONTINUOUS POSITIVE AIRWAY PRESSURE AND NONINVASIVE VENTILATION

Although mechanical ventilation is the primary treatment for respiratory failure in most preterm babies, there is a concern that it is a major contributor to lung injury. This has led to a growing interest in noninvasive forms of respiratory support in the belief that this will reduce the need for mechanical ventilation and its associated complications. The two major types of noninvasive neonatal respiratory support modalities are continuous positive airway pressure (CPAP) and nasal intermittent positive pressure ventilation (NIPPV). One other form of noninvasive respiratory support is continuous negative extra thoracic pressure (CNEP) but its use has been largely abandoned.

Physiology of Continuous Positive Airway Pressure

When used to treat respiratory distress syndrome (RDS), CPAP prevents collapse of the alveoli at end expiration, maintaining some degree of alveolar inflation. It thus decreases the work of breathing in accordance with LaPlace's law, in which the pressure required to overcome the collapsing forces generated by surface tension is reduced because the radius of curvature is greater when the alveolus is partially inflated. In this way, CPAP helps maintain functional residual capacity (FRC) and facilitate gas exchange.

CPAP also helps maintain upper airway stability by stenting the airway and decreasing obstruction. It may also augment stretch receptors and decrease diaphragmatic fatigue, and thus be useful in treating apnea of prematurity.

Complications of Continuous Positive Airway Pressure

Excessive CPAP may contribute to lung overinflation and increase the risk for air leaks. It can increase intrathoracic pressure and decrease venous return and cardiac output. If set too high, CPAP may result in carbon dioxide retention and impaired gas exchange. Gastric distention is a commonly encountered problem and can be at least partially alleviated by placement of an orogastric tube.

Care must be taken to avoid soft tissue injury, particularly to the nasal mucosa, nasal septum, and philtrum. Complications may also be associated with the fixation devices. Earlier reports of cerebellar hemorrhage associated with occipital fixation led to the virtual abandonment of CPAP for nearly two decades.

Nasal Continuous Positive Airway Pressure

CPAP is a form of continuous distending pressure (CDP), which is defined as the maintenance of increased transpulmonary pressure during the expiratory phase of respiration. When positive pressure is applied to the airways of spontaneously breathing infants, it is called continuous positive airway pressure, whereas distending pressure applied to a mechanically ventilated infant is called positive end-expiratory pressure (PEEP). Thus both CPAP and PEEP are types of CDP (although not technically a form of ventilation), which provide low-pressure distention of the lungs and prevent the collapse of alveoli at the end of expiration. CDP helps maintain FRC and thus facilitates gas exchange throughout the respiratory cycle. CPAP also supports the breathing of premature infants in a number of other ways including abolition of upper airway occlusion and decreasing upper airway resistance, enhancement of diaphragmatic tone and activity, improvement in lung compliance and decrease in lower airway resistance, increase in tidal volume delivery by improving pulmonary compliance, conservation of surfactant at the alveolar surface, and reduction in alveolar edema.[52]

CPAP may be administered invasively through an indwelling endotracheal tube, or it may be provided noninvasively using a variety of different nasal interfaces. This is referred to as nasal CPAP (NCPAP). Long nasopharyngeal tubes are still used in some centers but have the disadvantage of high resistance and therefore a large reduction in delivered pressure. They are also difficult to suction. Single nasal prongs are usually cut from endotracheal tubes and passed 1 to 2 cm into one nostril with about 3 cm residing externally. Although resistance is usually less than with nasopharyngeal tubes, it is still high with this device and there is a loss of pressure from the other nostril. Nasal masks are now used in the belief that they reduce trauma to the nostrils. However, it is often difficult to produce a good seal without undue pressure, which may still cause injury in the region between the nasal septum and the philtrum. Short binasal prongs are available in several designs; all have two short tubes that provide the least resistance of any other nasal interface. Current meta-analysis shows that short binasal prongs are more effective at maintaining extubation and preventing reintubation than single nasal prongs.[22]

Methods of Generating Continuous Positive Airway Pressure

See Box 44-4.

The gas mixture delivered by CPAP is derived from either continuous or variable flow. Continuous flow CPAP consists of gas flow generated at a source and directed against the resistance of the expiratory limb of the circuit. Ventilator-derived CPAP and bubble or underwater CPAP are examples of continuous flow devices, whereas infant flow drivers (flow-driven CPAP) and Benveniste valve CPAP are examples of variable-flow devices.

Flow-Driven Continuous Positive Airway Pressure

Flow-driven CPAP is a prototype of variable-flow CPAP. It uses a dedicated flow driver and gas generator with a fluidic-flip mechanism to deliver variable-flow CPAP. The principle is the Bernoulli effect, which directs gas flow toward each nostril, and the Coanda effect, which causes the inspiratory flow to flip and leave the generator chamber via the expiratory limb during exhalation. This assists spontaneous breathing and reduces the work of breathing by lowering expiratory resistance and maintaining stable airway pressure. Flow-driven CPAP can be delivered using binasal prongs or a nasal mask.

BOX 44–4 Methods of Providing Continuous Positive Airway Pressure

Ventilator-derived CPAP
Flow-driven CPAP
Bubble (underwater) CPAP
High-flow nasal cannula CPAP

BOX 44–5 Clinical Indications for Continuous Positive Airway Pressure

Delivery room resuscitation
Management of respiratory distress syndrome
Postextubation support
Apnea
Mild upper airway obstruction

Bubble Continuous Positive Airway Pressure

Underwater bubble continuous positive airway pressure (BCPAP) is a continuous flow system used since the early 1970s. In this method, the blended gas is heated and humidified, and then delivered to the infant through a secured low-resistance nasal prong cannula. The distal end of the expiratory tubing is immersed underwater and the CPAP pressure generated is equal to the depth of immersion of the CPAP probe. It has also been proposed that chest vibrations produced by the bubbling may contribute to gas exchange. BCPAP is an effective and inexpensive option to provide respiratory support to premature babies. In a recent randomized, controlled trial, BCPAP was found to be at least as effective as flow-driven CPAP in postextubation management of babies with respiratory distress syndrome.[41]

Ventilator-derived CPAP is another conventional way to administer continuous flow CPAP. The CPAP is increased or decreased by varying the ventilator's expiratory orifice diameter. The exhalation valve works in conjunction with other controls, such as flow control and pressure transducers, to maintain the CPAP at the desired level.

High-Flow Nasal Cannula

Flow of gas in excess of 2 L/min through a small nasal cannula provides some degree of CPAP. Because it is easy to use, utilization of this technique has increased in many units. However, the major problem with this technique is that the CPAP level is usually not measurable in clinical practice and has been shown to be highly variable depending on the leak at the nose or mouth.[52] Nasal leaks are indeed problematic, because the nasal cannula fits loosely in the nostrils. The reintubation rate in babies receiving high-flow nasal cannula CPAP is significantly higher compared with rates for NCPAP. A recently introduced device, which provides CPAP by using heated and humidified gas at very high flow rates (e.g., 7 L/min) had some degree of popularity until problems with infection and air leak were found.

Clinical Indications for Continuous Positive Airway Pressure in Newborns

See Box 44-5.

The clinical use of NCPAP in the neonate falls into one of several groups: (1) early use in resuscitation, (2) management of RDS, (3) postextubation care, (4) treatment of apnea, and (5) management of mild upper airway obstruction.

The only randomized trial of CPAP for resuscitation of newborns was conducted by Finer and colleagues in 2004. About 50% of infants required intubation for resuscitation, which was not affected by the use of CPAP or PEEP. The need for intubation was mostly dependent upon gestational age, with 100% of infants at 23 weeks and only 18% of infants at 27 weeks requiring intubation. By 7 days of age, 80% of infants had required intubation.[35]

With respect to the management of RDS, most of the available data arose from observational studies and suggest that CPAP may obviate the need for surfactant and avoid intubation in some babies. Most of the data are from the era preceding both surfactant and the widespread use of antenatal steroids. Since then, there have been a number of controlled trials, but they are either small in number or have used different protocols, making it difficult to derive meaningful conclusions. A recent multicenter international randomized trial suggests that NCPAP may be an acceptable alternative to endotracheal intubation in the delivery room but a number of issues remain unresolved.[53] Pneumothorax developed in three times as many babies receiving CPAP than in those who were intubated. Longer-term outcome data of the studied infants are not yet available. An alternative strategy of intubation, surfactant administration, and rapid extubation to NCPAP has shown equivalent outcomes to a prophylactic surfactant strategy. The SUPPORT study demonstrated that a purely CPAP-based strategy could be effective in very immature babies.[73a]

CPAP is an established method of providing respiratory support following extubation from mechanical ventilation. Multiple studies confirm that postextubation CPAP enhances the success rate of extubation and decreases the need for reintubation.[17,18]

Practical Problems of Nasal Continuous Positive Airway Pressure

Despite its widespread use, a number of problems still persist.[34] Nasal prongs rarely fit tightly into the nostrils, thus resulting in gas leak and inability to maintain a baseline pressure. The set CPAP level is rarely maintained in the pharynx. The best way to reduce nose leak is to ensure that the prongs are of sufficient size to snugly fit the nostrils without making them blanch. A chin strap can be used to reduce leaks around the mouth, but it is not simple to use in practice.

Nasal trauma is also a common problem with NCPAP. It is mostly caused by incorrect positioning of the prongs. To prevent injury, the nasal device must not be pushed up against the columella. Selection of appropriate size prongs, constant nursing vigilance, and attention to correct positioning are necessary to prevent nasal injury during NCPAP.

Noninvasive Nasal Ventilation

Methods of noninvasive ventilation include nasal intermittent positive pressure ventilation (NIPPV), synchronized nasal intermittent positive pressure ventilation (SNIPPV), and synchronized bilevel CPAP (SiPAP). In all of these modalities, ventilator inflations augment NCPAP while PEEP, peak inspiratory pressure (PIP), respiratory rate, and inspiratory time can all be manipulated. Terminology used to describe NIPPV is not standardized and may be confusing. SiPAP, a form of NIPPV, is also termed *biphasic* or *bilevel nasal CPAP*. There are no clinical trials to confirm that a bilevel approach to noninvasive respiratory support with SiPAP is more beneficial than the conventional NCPAP.

The mechanism of action of NIPPV remains unclear. It is not known whether mechanical inflations during NIPPV are transmitted to the lungs; clinical studies show contradictory results. Other trials also found no differences in tidal volume or minute volume when comparing NCPAP with SNIPPV. Similarly, there are conflicting reports on work of breathing, pulmonary mechanics, and thoracoabdominal synchrony during comparisons of NCPAP with SNIPPV.[20] The availability of synchronized NIPPV has decreased because the sole device capable of providing it has been withdrawn from the market.

Clinical Indications for Nasal Intermittent Positive Pressure Ventilation

Several studies have compared nonsynchronized NIPPV with NCPAP for treatment of apnea in premature infants, but showed no advantage of NIPPV over NCPAP. Trials have also compared SNIPPV with NCPAP following extubation and found a significant reduction in extubation failure using SNIPPV. Studies have also assessed NIPPV as a primary strategy to treat RDS while avoiding intubation. These studies reported improved carbon dioxide removal, reduced apnea, and shorter duration of ventilation in the NIPPV group. Nonetheless, these are small studies, and they used sufficiently different protocols to prevent generalizable conclusions. Moreover, the understanding of, and evidence for, NIPPV is limited. Large controlled studies are needed to resolve this conundrum.

INDICATIONS FOR ASSISTED VENTILATION

Mechanical ventilation is intended to take over or assist the work of breathing in babies who are unable to support effective pulmonary gas exchange on their own. The causes for respiratory insufficiency may be pulmonary, such as respiratory distress syndrome or meconium aspiration syndrome, extrapulmonary, such as airway obstruction or compression, or neurologic, such as central apnea or neuromuscular disease. Respiratory failure may also accompany other system derangements, including sepsis or shock.

Indications for assisted ventilation may be thought of as absolute and relative (Box 44-6). Absolute indications include entities encountered in the delivery room, such as the failure to establish spontaneous breathing despite bag and mask ventilation, persistent bradycardia despite positive pressure ventilation by mask, or the presence of major anomalies, such as diaphragmatic hernia or severe hydrops fetalis, wherein there is a high likelihood of immediate respiratory failure. In the neonatal intensive care unit, sudden respiratory or cardiac collapse with apnea and bradycardia unresponsive to mask ventilation and massive pulmonary hemorrhage are two examples of absolute indications.[39]

BOX 44–6 Indications for Assisted Ventilation

ABSOLUTE INDICATIONS

Failure to initiate or sustain spontaneous breathing
Persistent bradycardia despite bag-mask ventilation
Presence of major airway or pulmonary malformations
Sudden respiratory or cardiac collapse with apnea/bradycardia

RELATIVE INDICATIONS

High likelihood of subsequent respiratory failure
Surfactant administration
Impaired pulmonary gas exchange
Worsening apnea unresponsive to other measures
Need to maintain airway patency
Need to control carbon dioxide elimination

Relative indications may be based on clinical judgment, such as intubating very preterm babies for prophylactic or early surfactant administration, or they may be based on an objective assessment of impaired gas exchange as evidenced by abnormal blood gases. Various recommendations exist to define respiratory failure severe enough to warrant assisted ventilation. In general, the easiest of these is the so-called 50-50 rule, wherein hypoxemia is defined as a failure to maintain an arterial oxygen tension of 50 mm Hg with a fraction of inspired oxygen of 0.5 (50%) or greater and hypercapnia is defined as an arterial carbon dioxide tension greater than 50 mm Hg. Some have suggested that the arterial carbon dioxide tension criterion should be coupled with a pH value, such as less than 7.25. Additional relative indications for assisted ventilation include the stabilization of infants who are at risk for sudden deterioration, such as preterm infants with apnea unresponsive to CPAP or methylxanthines, severe systemic illness, such as sepsis, the need to maintain airway patency, such as meconium aspiration syndrome or tracheobronchomalacia, or the need to maintain control of carbon dioxide elimination, such as persistent pulmonary hypertension or following severe hypoxic-ischemic brain injury.

GENERAL PRINCIPLES OF ASSISTED VENTILATION

Oxygenation

The two major factors responsible for oxygenating the blood are the fraction of inspired oxygen and the pressure to which the lung is exposed (Box 44-7). The role of inspired oxygen can be understood from the alveolar gas equation

BOX 44–7 Determinants of Oxygenation

Fraction of inspired oxygen
Mean airway pressure
Positive end-expiratory pressure (PEEP)
Peak inspiratory pressure (PIP)
Inspiratory time
Frequency
Gas flow rate

(see Part 2 of this chapter). Oxygenation is also proportional to mean airway pressure (mean Paw), which is the average pressure applied to the lungs during the respiratory cycle and is represented by the area under the curve for the pressure waveform. Inflation of the lung exposes more of the pulmonary surface area to alveolar gas. Thus, those factors that increase mean airway pressure will, up to a certain point, improve oxygenation (Fig. 44-34).[13]

The most direct impact comes from PEEP because it is applied throughout the respiratory cycle. PEEP is the baseline pressure, the lowest level to which airway pressure falls. It is used to take advantage of LaPlace's law, by maintaining some degree of alveolar inflation during expiration, thus reducing the pressure necessary to further inflate the alveolus during inspiration. There is a 1:1 relationship between PEEP and mean Paw: For every cm H_2O increase in PEEP, there is a cm H_2O increase in mean Paw. Excessive PEEP is potentially harmful. It may overdistend the alveoli, increasing the risk of air leaks; it may impede venous return and cardiac output; it may decrease the amplitude, leading to carbon dioxide retention (see later).[11]

PIP also increases the mean Paw, but this is proportional to the inspiratory time (T_I) or duration of positive pressure. PIP is the driving pressure and establishes the upper limit of the amplitude. Excessive PIP poses many of the same risks as excessive PEEP, including hyperinflation (overdistention) of the lung, leading to excessive stretch of the alveolar units (barotrauma or volutrauma); high intrathoracic pressure with decreased venous return and cardiac output; and air leaks. Additionally, if PIP, PEEP, or both are inadequate, there may be alveolar atelectasis and resultant damage to the lung from cyclic opening and closing of lung units, a process referred to as *atelectrauma*.[16]

Mean Paw is also affected by T_I and the duration of positive pressure. As T_I increases, the mean Paw also increases if all other parameters are held constant. Similarly, on machines in which the inspiratory/expiratory (I/E) ratio is adjusted, mean Paw increases as the inspiratory phase is lengthened or the expiratory phase is shortened. If the T_I is too long, however, there is an increased risk of gas trapping, inadvertent PEEP, and air leak. If it is too short, there may be inadequate lung expansion, air hunger, and patient-ventilator asynchrony, leading to inefficient gas exchange.

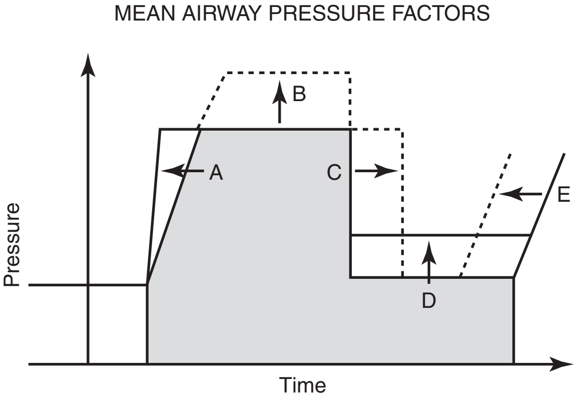

Figure 44–34. Graphic representation of determinants of mean airway pressure. The mean airway pressure is the area under the curve (*shaded*). Note the effects of increasing the rise time (*A*), peak inspiratory pressure (*B*), inspiratory time (*C*), and positive end-expiratory pressure (*D*), and of decreasing the expiratory time (*E*).

Changes in the ventilator rate have a slight effect on mean Paw. At faster rates, the mean Paw rises, because there are more breaths delivered per minute, and the cumulative area under the curve per unit of time increases. Rapid rates may result in incomplete emptying of the lung, with gas trapping, inadvertent PEEP, and lung hyperinflation.

Finally, circuit gas flow also impacts mean Paw. If the T_I is held constant, more volume (and hence higher pressure) is delivered as flow is increased. If the flow is set too high, turbulence, incomplete emptying of the lung, inadvertent PEEP, and hyperinflation may occur.[63] If the flow is set too low, air hunger and asynchrony result. The injurious effects of improper airway flow have been referred to as *rheotrauma*.[25]

Ventilation

Ventilation refers to carbon dioxide removal. Its two primary determinants are tidal volume and frequency (Box 44-8).[11] Tidal volume is determined by the amplitude of the mechanical breath, or the difference between the peak (PIP) and baseline (PEEP) pressures. During conventional mechanical (CMV) ventilation, carbon dioxide removal is the product of tidal volume and frequency. Clinically, this is usually expressed as the minute volume, or mL/kg/min of exhaled gas. It is also important to consider the contribution of spontaneous breathing to minute ventilation (which is not always measured), and that pulmonary bloodflow is also a key element in carbon dioxide removal, as well as oxygenation. During HFV, carbon dioxide removal is the product of frequency and the *square* of the tidal volume.[8] Thus small changes in amplitude may have a profound effect on arterial carbon dioxide tension (see later).

Control of ventilation during patient-triggered ventilation requires an understanding of the physiology of gas exchange. Most newborns have intact chemoreceptors and seek to maintain normocapnia. This is accomplished by adjustments in minute ventilation. Thus if the clinician sets the amplitude too low, the baby compensates by increasing the spontaneous (and hence, triggered) breathing rate. Conversely, if the

EXPIRATORY TIME (OR I/E RATIO)

amplitude is set too high, the infant's hypercapnic drive is abolished and the baby "rides" the ventilator rate.[27]

Carbon dioxide tension is affected by minute ventilation, which in turn is the product of tidal volume and frequency during CMV. Of these two parameters, adjustment in tidal volume (by adjusting the amplitude) has a more predictable effect on minute ventilation.[11]

Time Constant

Use of mechanical ventilators requires an understanding of the pulmonary time constant. The pulmonary time constant refers to the time required to allow pressure and volume equilibration of the lung (see Part 2). Mathematically, the time constant is the product of compliance and resistance. When the lung is stiff (low compliance) and has limited expansibility, such as occurs during RDS, it takes less time to fill and empty than it does at higher compliance. This pattern is clinically illustrated by observing the spontaneous breathing pattern of an infant with RDS not requiring assisted ventilation. Early on, when compliance is poor, the baby breathes rapidly and takes shallow breaths. As the disease process remits, compliance improves, and the baby breathes more slowly and takes deeper breaths.

If expiratory time is set at one time constant, approximately 63% of the change in pressure or volume occurs; if it is lengthened to three time constants, changeover increases to 95%, and at a five time constant length, it approaches 99%. Thus setting the expiratory time at less than three to five times the length of the time constant increases the risk of gas trapping and potentially inadvertent PEEP and alveolar rupture.[12]

Classification of Mechanical Ventilators

Over the past decade, newer mechanical ventilation devices based on sound physiologic principles have been introduced into neonatal practice. The proliferation of devices and techniques has caused confusion about nomenclature and classification, which are frequently device specific. In a general sense, mechanical ventilators can be divided into two groups, those that deliver physiologic tidal volumes, often referred to as *conventional mechanical ventilators*, and those that deliver tidal volumes that are less than physiologic dead space, referred to as *high-frequency devices*.

Among conventional mechanical ventilators, it is advisable to use a simple hierarchical classification to describe devices according to the variables they use (Fig. 44-35). These variables fall into two categories, those that control the type of ventilation (called *ventilatory modalities*) and those that determine the breath type (called *ventilatory modes*).[10,14,37]

Control Variables (Ventilatory Modalities)

At any one time, the ventilator can control only a single variable: time, pressure, or volume. However, the same ventilatory device can operate using different control variables at different times. Ventilatory modalities can target either pressure or volume as the primary variable. Because volume is the integral of flow, volume- and flow-controlled ventilation are actually the same. When pressure is controlled, volume fluctuates according to the compliance of the lungs; conversely, when volume is controlled, pressure fluctuates as a function of compliance.[76]

Phase Variables (Ventilatory Modes)

The mechanical breaths delivered by the ventilator have four phases and more than one variable can be used to design the type of breath to suit the underlying lung mechanics or pathophysiology. The first of these is the variable that initiates or triggers inspiration (trigger). The second is the variable that is used to limit the inspiratory gas flow (limit). The third is the variable that changes inspiration to expiration and vice versa (cycle). The final is the variable that maintains the baseline pressure during expiration (PEEP).[76]

A number of variables can be used to trigger a breath. In the past, most neonatal ventilators used time to start inspiration. The clinician programmed either a set inspiratory time or ventilator rate and inspiratory/expiratory ratio, and the exhalation valve would open and close according to the lapse of time. More recently, other triggering variables have been introduced, allowing for the synchronization of the onset of mechanical breaths to spontaneous breathing. The clinician can set a threshold flow or pressure, above which the ventilator initiates a mechanical breath. These variables are used as a surrogate for spontaneous effort and include pressure or flow, with time as a backup. Most present ventilators use flow-triggering devices because this requires less effort to trigger and is thus associated with less work of breathing.[26]

The limit variable restricts the expiratory flow to a preset value. Traditionally, pressure has been used as a limit variable, but volume and flow are other variables that can limit inspiratory flow. True volume limitation is difficult to achieve

because cuffed endotracheal tubes are not used, and there is almost always some degree of volume loss around the endotracheal tube.

The cycling mechanism is the variable used to end inspiration. Most neonatal ventilators, including high-frequency ventilators, are time-cycled, but changes in airway flow may also be used to end the inspiratory phase.[26] Termination of inspiration occurs when decelerating inspiratory flow has reached a preset percentage of peak inspiratory flow. At this point, the exhalation valve opens and expiration begins. Flow cycling more accurately mimics the physiologic breathing pattern and allows for the mechanical breath to be fully synchronized to the spontaneous breath during both inspiration and expiration. Changes in transthoracic electrical impedance that occur during spontaneous respiration can also be used to generate a trigger signal.[68] Thus triggering during both active inspiration and active expiration can achieve total synchronous breathing between the baby and the ventilator.

Modes of Ventilation

Using different phase variables, which are interchangeable, a variety of ventilatory modes can be generated, which are applicable to both pressure- and volume-controlled modalities. The commonly used ventilatory modes are intermittent mandatory ventilation (IMV), synchronized intermittent mandatory ventilation (SIMV), assist/control (A/C) ventilation, and pressure support ventilation (PSV).[42] Figure 44-36 is a graphic comparison of IMV and SIMV demonstrating the effects of asynchronous ventilation.

INTERMITTENT MANDATORY VENTILATION

IMV delivers mechanical breaths at a rate set by the clinician. Breaths are provided at regular intervals and are not influenced by spontaneous breathing. The baby may breathe spontaneously with, between, or even against the mechanical breath, supported only by PEEP, and patient-ventilator dyssynchrony can be a major problem, resulting in a wide variability in delivered tidal volume. Efforts to reduce dyssynchrony include increasing the rate to override the spontaneous drive and "capture" the baby, generous use of sedatives, and, in some instances, the administration of skeletal muscle relaxants.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION

Synchronized intermittent mandatory ventilation (SIMV) is a mode in which the onset of mechanical breaths is synchronized to the onset of spontaneous breaths if the patient begins to breathe within a timing window. As a result, mechanical breaths are not delivered as regularly as in IMV, but vary slightly according to the baby's own breathing pattern. In between the mechanical breaths, the baby may breathe spontaneously, but again, the spontaneous breaths are supported only by PEEP unless pressure support is used (see later). In time-cycled SIMV, synchrony between mechanical and spontaneous breathing occurs only during inspiration, because the inspiratory time for both mechanical and spontaneous breaths may be different. This discrepancy can be offset by using flow cycling, in which synchrony occurs during both inspiration and expiration.

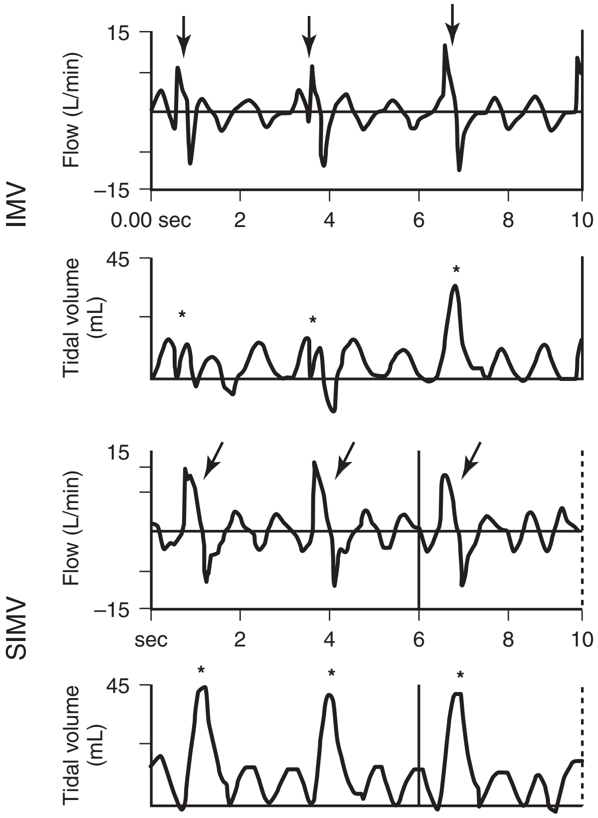

Figure 44–36. Comparison of tidal volume delivery and flow during intermittent mandatory ventilation (IMV) and synchronized intermittent mandatory ventilation (SIMV). Note the tremendous variability in delivered tidal volume (noted by *asterisks*) during IMV breaths *(vertical arrows)* as compared to SIMV breaths *(diagonal arrows)*. Dyssynchronous breathing during IMV leads to inefficient gas exchange.

ASSIST/CONTROL

In the A/C mode, the ventilator delivers a mechanical breath each time the patient's inspiratory effort exceeds the preset threshold criterion. When the patient triggers the ventilator to deliver a mechanical breath, the breath is said to be *assisted*. This mode also provides the safety of a guaranteed minimal mechanical breath rate (the control rate, set by the operator) in case no patient effort occurs or is detected. A/C breaths can be time-cycled or flow-cycled. During A/C ventilation, as long as the baby breathes above the control rate, lowering the control rate has no effect on the total respiratory rate, and thus the reduction of pressure should be the primary weaning strategy (see later).[62]

PRESSURE SUPPORT VENTILATION

Pressure support ventilation was developed to help intubated patients overcome the imposed work of breathing created by the narrow lumen (high resistance) endotracheal tube, circuit dead space, and demand valve (if one is being used). It is, however, a *spontaneous* breath mode. Spontaneous breaths that exceed the trigger threshold result in the delivery of additional inspiratory pressure to a limit set by the clinician.

These breaths are flow-cycled, but for safety purposes they may be time-limited. PSV is most commonly used in conjunction with SIMV to support spontaneous breathing between SIMV breaths with something more substantial than PEEP (Fig. 44-37). If the pressure limit of the PSV breath is adjusted to provide a full tidal volume breath, it is referred to as PS_{max}. If the pressure applied is just enough to overcome the imposed work of breathing, it is referred to as PS_{min}. PSV is a relatively new neonatal mode and is being actively explored. It appears that it is most commonly used as a weaning strategy with low-rate SIMV.[60]

Pressure-Targeted Modalities

Pressure-targeted modalities are characterized by limiting the amount of pressure that can be delivered during inspiration. The clinician sets the maximum pressure and the ventilator does not exceed this level. The volume of gas delivered to the baby varies according to lung compliance and the degree of synchronization between the baby and the ventilator. If compliance is low, less volume is delivered than if compliance is high.[61] In IMV, tidal volume fluctuates depending on whether the baby is breathing with the ventilator or against it.

There are three main pressure targeted modalities: pressure-limited ventilation (PLV), pressure control ventilation (PCV), and pressure support ventilation (PSV), which is also a mode. All three are pressure-limited. Some devices allow both PLV and PCV to be time- or flow-cycled. PSV is flow-cycled but time-limited. Inspiratory flow during PLV is continuous and is set by the clinician. During both PCV and PSV, inspiratory flow is variable and is related to lung mechanics and patient effort. It accelerates rapidly early in inspiration, then decelerates quickly, producing a characteristic waveform.[23] Some devices allow modulation of the accelerating portion by offering an adjustable rise time. This enables “fine tuning” of flow to avoid pressure overshoot or flow starvation and helps achieve optimal hysteresis of the pressure-volume loop.

PLV has been used to treat neonatal respiratory failure for almost a half century. It was developed from adult ventilators by adding continuous flow to the bias circuit to allow the baby to have a fresh source of gas from which to breathe between mechanical breaths. It is relatively easy to use and was presumed to be safe because the delivered inspiratory pressure could be limited, thus reducing the risks associated with barotrauma. Although the inspiratory pressure is very consistent on a breath-to-breath basis, the delivered tidal volume fluctuates. In the postsurfactant era, lung compliance may vary considerably following the administration of surfactant, and unless the clinician is vigilant, increasing tidal volume can lead to overexpansion and volutrauma.

PCV was recently introduced into neonatal ventilators. It differs from PLV primarily in the manner in which flow is regulated. This produces a waveform that accelerates then decelerates rapidly. A rapid rise in flow early in inspiration leads to earlier pressurization of the ventilator circuit and delivery of gas to the baby early in inspiration. Intuitively, this should be beneficial in disease states characterized by homogeneity and the need for a higher opening pressure, such as RDS. Variable flow should be advantageous when resistance is high, such as when a small endotracheal tube is used. The relative novelty of PCV has thus far precluded adequate comparison to PLV.

Both PLV and PCV are used as mandatory modes (IMV, SIMV) or A/C. PSV is a spontaneous mode; that is, it is applied to spontaneous breaths the baby takes between mandatory mechanical breaths to support spontaneous breathing and overcome the imposed work of breathing created by the narrow lumen endotracheal tube, circuit dead space, and

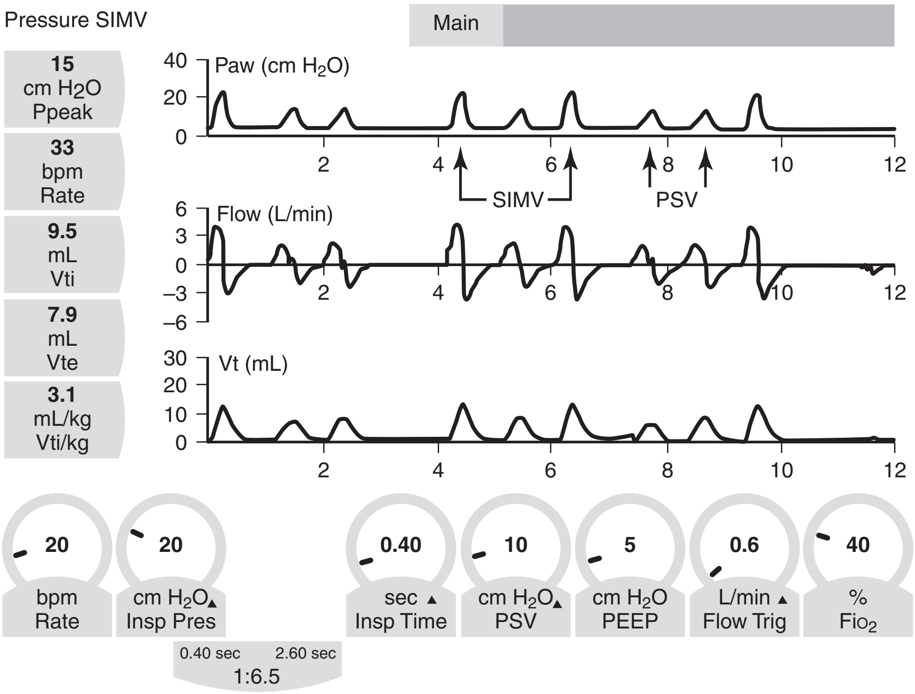

Figure 44–37. Graphic representation of the combined use of synchronized intermittent mandatory ventilation (SIMV) and pressure support ventilation (PSV), in which additional inspiratory pressure is applied to spontaneous breaths to help overcome the imposed work of breathing.

demand valve (if one is used). Because it is patient-triggered and flow-cycled, it is completely synchronized to the baby's own breathing; thus the baby controls the rate and the inspiratory time. The clinician sets the pressure level to augment spontaneous breathing. PSV can be used in conjunction with SIMV, or in patients with reliable respiratory drive, it may be used as a primary modality.[24] There is an evolving body of evidence that PSV is both safe and efficacious.* Still to be determined is the best way to apply PSV as a weaning tool. Table 44-2 compares the characteristics of pressure-targeted modalities.

Volume-Targeted Modalities

Broadly speaking, volume-targeted ventilation can be provided in several ways. Volume controlled ventilation (VCV), targets a set tidal volume, which is delivered irrespective of lung compliance or the pressure required to deliver it (pressure may be limited for safety reasons). Hybrid ventilators are essentially pressure-targeted but aim to deliver the tidal volume within a set range using computer-controlled feedback mechanisms. Finally, standard pressure-targeted ventilation can function in a quasi volume-targeted capacity if strict and vigilant attention is paid to volume delivery.[19]

VOLUME-CONTROLLED VENTILATION

The first ventilator designed specifically for volume-targeted ventilation in infants was the Bourns LS 104-150, which was modified from an adult ventilator. Because of many problems, including a high trigger sensitivity, long response times, and lack of continuous flow during spontaneous breathing, limited rate, poor circuit design, and the inability to measure the small tidal volumes, this device (and VCV) fell out of favor in the early 1980s. Technological advances in the 1990s enabled reintroduction of VCV to neonatal and pediatric patient populations. The new ventilators incorporate sophisticated devices to trigger, deliver, and accurately measure the tiny tidal volumes required by infants weighing as little as 500 g.

VCV for newborns differs from "adult" volume-cycled ventilation, in which inspiration is terminated and the machine is cycled into expiration when the specific target tidal volume has been delivered. However, the use of uncuffed endotracheal tubes in newborns results in some degree of gas leak around the tube and precludes the ability to cycle based on a true delivered tidal volume. Thus *volume cycling* is a misnomer in neonatal ventilation, and the terms *volume-controlled, volume-targeted,* or *volume-limited* better describe this modality. Many current ventilators provide the option of using a leak compensation algorithm to at least partially offset this problem.

During VCV, there is also a discrepancy between the volume of gas leaving the ventilator and that reaching the proximal airway which results from compression of gas within the ventilator circuit. This is referred to as compressible volume loss, which is greatest when pulmonary compliance is lowest. The use of semirigid circuits may help offset this. Compressible volume is also affected by humidification. It is, therefore, critical that the delivered tidal volume is measured as close to the proximal airway as possible.

The principal feature of VCV is that it delivers the set tidal volume regardless of the underlying lung compliance by automatically adjusting the PIP (Fig. 44-38). Another important feature of VCV that differentiates it from PLV is the way that gas is delivered during the inspiratory phase.[74] In traditional VCV, a square flow waveform is generated and peak volume and pressure delivery are achieved at the end of inspiration (Fig. 44-39). These may be thought of as "back end" loaded breaths. In comparison, in PLV, the gas flow pattern accelerates rapidly, then decelerates, resulting in the achievement of peak pressure and volume delivery early in inspiration. This produces a "front end" loaded breath. Because these are very different, certain disease states might be more amenable to one form than the other.

Detractors of VCV have argued that, unlike the limited pressure used in PLV, VCV may use a high inflation pressure to deliver the preset volume in cases of decreased compliance. This anxiety in the past arose because of the perceived risks of barotrauma and its consequences associated with high PIP. However, because it has become clear that it is not necessarily the high pressure but rather the excessive tidal volume (volutrauma) that causes lung injury,[31] attention to controlling tidal volume delivery has become an essential part of neonatal ventilation. It should also be realized that high peak pressure associated with fixed-flow delivery in VCV is a reflection of proximal airway pressure rather than alveolar pressure. When the compliance of the patient's lungs improves (increases), the ventilator generates less pressure to deliver the same tidal volume, thus leading to an automatic reduction of the PIP. It is also a misconception that pressure-limited ventilation of infants is superior to VCV because it maintains a constant airway pressure in the presence of leaks around uncuffed endotracheal tubes. The reasoning seems to be that constant pressure implies that the delivered volume remains constant, but this is not true in that leaks around the uncuffed endotracheal tube also occur with PLV. Some VCV devices provide a way to compensate for leaks by adding

TABLE 44–2 Characteristics of Pressure-Targeted Modalities

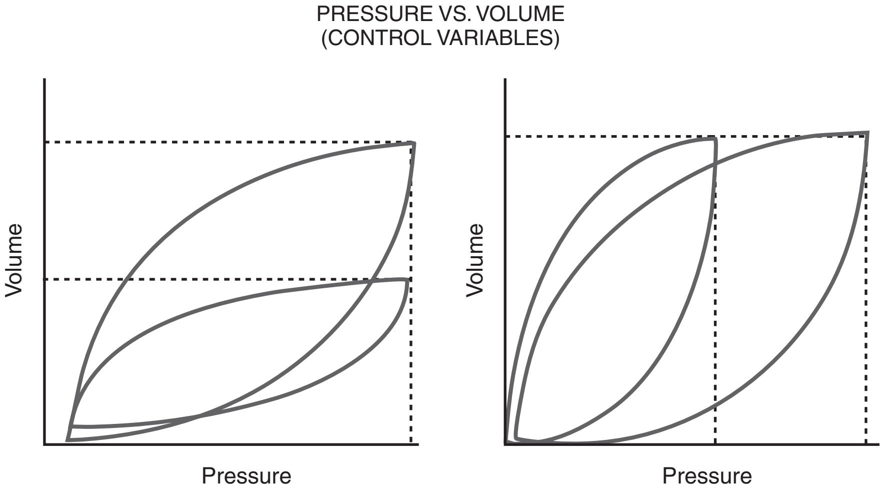

Figure 44–38. Responses to changes in compliance in pressure versus volume-targeted ventilation. In pressure-targeted ventilation, change in pulmonary compliance results in a change in delivered tidal volume, whereas pressure remains constant (left). In volume-targeted ventilation, changes in compliance result in a change in pressure, while delivered tidal volume remains constant (right).

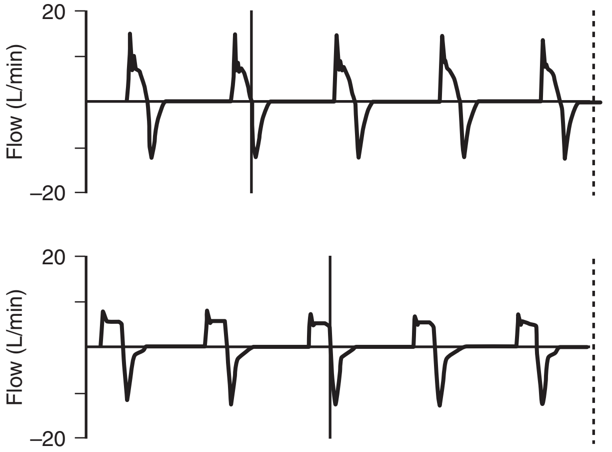

Figure 44–39. Flow waveforms for pressure-targeted *(top)* and volume-targeted *(bottom)* ventilation. Pressure-targeted ventilation produces a spiked waveform with rapid acceleration and deceleration of flow, producing peak pressure and volume delivery early in inspiration. Volume-targeted ventilation produces a characteristic "square wave," with constant or plateau flow. This results in peak pressure and volume delivery at the end of inspiration.

additional flow to the circuit to automatically maintain a stable baseline pressure.

VCV, like PLV, can be provided as IMV, SIMV, and A/C ventilation. It may also be combined with PSV during SIMV and even A/C in some devices.[61]

Hybrid Volume Targeted Ventilation

Some newer devices use a blended approach to volume targeting. They are primarily pressure-targeted ventilators but involve computerized servocontrolled ventilation, in which a ventilator algorithm adjusts the rise and fall of pressure to produce tidal volume delivery within a set range. These include Volume Guarantee (VG), Pressure Regulated Volume Control (PRVC), and Volume Assured Pressure Support (VAPS). VG and PRVC use the tidal volume of previous breaths as a reference, but follow-up adjustments in PIP take place on four to six breath averages. VAPS makes intrabreath adjustments of pressure, inspiratory time, or both until the desired volume has been provided. These hybrid forms try to achieve the same goal, the optimization of tidal volume delivery, although each has a different mechanism. Clinicians must familiarize themselves with the specific features of individual machines in order to maximize safety and efficacy.

VOLUME GUARANTEE VENTILATION

VG ventilation is a commonly used form of volume targeting.[46] It is a dual-loop, synchronized, pressure-targeted modality of ventilation with microprocessor-based adjustments in pressure to ensure adequate tidal volume delivery. The operator chooses a target tidal volume and selects a pressure limit up to which the inspiratory pressure (the working pressure) may be adjusted. The machine uses the exhaled tidal volume of the previous breath as a reference to adjust the working pressure up or down over the next few breaths to achieve the target volume. The auto-feedback mechanism is an improvement in design but has some limitations. For example, as adjustments to PIP are made in small increments to avoid overcompensation, and as adjustments are based on the exhaled tidal volumes, the delivered tidal volume may not compensate for large breath-to-breath fluctuations in the presence of large leaks. Moreover, as catch-up adjustments in pressures occur every few breaths, it may not work if the ventilator rate is set at low levels such as those used during weaning. In this context, the term "guarantee" is somewhat misleading.

VG can only be used in conjunction with patient-triggered modes, that is, A/C, SIMV, and PSV. The inspiratory pressure is set at the upper desired pressure limit. If this pressure is reached and the set tidal volume has not been delivered, an alarm sounds. Automatic pressure changes are made in increments to avoid overcompensation. No more than 130% of the target tidal volume is supposed to be delivered. The usual starting target is a tidal volume of 4 to 5 mL/kg. The pressure limit is set approximately 15% to 20% above the peak pressure needed to constantly deliver the target tidal volume. Most infants can be extubated when they consistently maintain tidal volume at or above the target value with delivered

PIP less than 10 to 12 cm H_2O and with good sustained respiratory effort.

PRESSURE-REGULATED VOLUME CONTROL VENTILATION

PRVC is another modality of ventilation that attempts to combine the benefits of PLV and VCV.[9] It is a flow-cycled modality that offers the variable flow rate of pressure control ventilation with a targeted tidal volume. Like VG, PRVC is also a form of closed loop ventilation in which pressure is adjusted according to the tidal volume delivered. The clinician selects a target tidal volume and the maximum pressure allowed to deliver the tidal volume. The microprocessor of the ventilator attempts to use the lowest possible pressure with a decelerating flow waveform to deliver the set tidal volume. The first breath is delivered at 10 cm H_2O above PEEP and is used as a test breath to enable the microprocessor to calculate the pressure needed to deliver the selected tidal volume based on the patient's compliance. The next three breaths are delivered at a pressure of 75% of the calculated pressure needed. If the targeted tidal volume is not achieved, the inspiratory pressure is increased by 3 cm H_2O for each breath until the desired tidal volume is reached. If targeted tidal volume is exceeded, the inspiratory pressure is decreased by 3 cm H_2O. Inspiratory pressure is regulated by the ventilator between the PEEP level and 5 cm H_2O below the clinician-set upper pressure limit. In PRVC, the pressure is adjusted based on the average of four breaths, so variations in delivered tidal volume still occur.

VOLUME ASSURED PRESSURE SUPPORT VENTILATION

VAPS is a hybrid modality of ventilation that optimizes two types of inspiratory flow patterns (VAPS = PSV + VCV), thus combining the advantages of both pressure and volume ventilation within a single breath and on a breath-to-breath basis.[6] It is best described as *variable flow volume ventilation*. VAPS can be used in either A/C or SIMV modes, or alone in babies with reliable respiratory drive. Spontaneous breaths begin as PSV breaths. The ventilator measures the gas volume delivered when the inspiratory flow has decelerated to the minimal set value. As long as the delivered volume exceeds the desired level (set by the clinician), the breath behaves like a pressure support breath and is flow-cycled. If the preset tidal volume has not been achieved, the breath transitions to a volume-controlled breath; the set flow persists and the inspiratory time is prolonged (and pressure may increase slightly) until the desired volume is reached. VAPS can be used both in the acute phase of respiratory illness, wherein the patient requires a substantial level of ventilatory support, and when a patient is being weaned from the ventilator, especially in the face of unstable ventilatory drive. The optimal flow acceleration varies with patient dynamics, patient demand, and patient circuit characteristics. Pulmonary graphics are an essential tool for making the appropriate adjustments with VAPS.

VOLUME SUPPORT VENTILATION

Volume support ventilation (VSV) is another hybrid modality combining features of PSV and PRVC.[9] It is intended for patients who are breathing spontaneously with sufficient respiratory drive. Similar to PRVC, breath rate, tidal volume, and minute volume are preselected by the clinician; however, inspiratory time is determined by the patient. Like PRVC, the ventilator algorithm increases or decreases the pressure limit by no more than 3 cm H_2O at a time. Adjustments are made in sequential breaths until the target tidal volume is achieved. The flow, pressure, and volume graphics for a volume-supported breath are similar to those of pressure-supported breaths; however, evidence for efficacy of volume support can only be assessed by evaluating sequential graphic presentations over time, as in PRVC. The tidal volume waveform increases in a stepwise fashion until the targeted volume is reached.

PRESSURE AUGMENTATION

Pressure augmentation is a hybrid modality that offers the benefit of matching the patient's flow demand while guaranteeing a minimal tidal volume. Pressure augmentation differs from PRVC in the following ways: (1) the preset tidal volume is only a minimum and the patient can breathe above this level, (2) the minimum tidal volume is guaranteed by adjustment in flow rather than pressure, which is fixed at a preselected level, and (3) adjustment to flow is made within each breath rather than several sequential breaths. Pressure augmentation is interactive with the patient and is dependent upon the patient's flow demand and lung dynamics. Pressure augmentation can be used in either the A/C or SIMV modes, where volume-controlled breaths are selected.

SUGGESTED VENTILATORY MANAGEMENT GUIDELINES

Initiation of pressure targeted ventilation is aimed at achieving adequate pulmonary gas exchange at the least possible pressure. Selection of pressure limited or pressure control ventilation should be based on the pathophysiology of the respiratory failure. When the lungs are very stiff (poor compliance), such as in RDS, and there is a need for a high opening pressure, pressure control may be advantageous because of the rapid pressurization of the ventilator circuit and delivery of gas flow early in inspiration. If parenchymal disease is less heterogeneous, pressure-limited ventilation with slower inspiratory flow may be safer. Rapidly moving gas preferentially ventilates the more compliant areas of the lung, perhaps contributing to ventilation-perfusion mismatch.

Pressure should be adequate to cause a visible rise in the chest wall during inspiration, and adequate breath sounds should be appreciated on auscultation. If measured, tidal volumes should be 4 to 7 mL/kg in preterm infants and 5 to 8 mL/kg in term infants.[55] PEEP is generally initiated at 4 to 6 cm H_2O, although higher levels are sometimes necessary. The selection of a mode is usually based on personal preference, although A/C offers the most support. The rate should be adjusted to normalize minute ventilation and achieve normocapnia.

The inspiratory time should be chosen according to the pulmonary time constant. Small babies with stiff lungs generally require short inspiratory times, which are proportional to birthweight,[70] Care must be taken to avoid gas trapping (see later).

The circuit (bias) flow rate should be adjusted to ensure that it is adequate to meet the PIP within the allotted inspiratory time, but it should not be too high or it may cause turbulence, inefficient gas exchange, inadvertent PEEP, and lung overdistention.

Brief summaries of the clinical management protocol for VCV and VG are listed in Table 44-3. In VCV (see Table 44-3), ventilation is generally initiated in the A/C mode using a desired inspiratory tidal volume of 4 to 8 mL/kg (measured at the proximal endotracheal tube) as the reference range to achieve the target blood gases. However, for monitoring and further adjustments in tidal volume delivery, expired tidal volume should be used as the reference as it provides a more accurate measurement of the gas delivery to the lungs. To start weaning, a combination of low rate SIMV (6 to 20 breaths/min) and PSV to augment spontaneous breathing seems best, because it compensates for the imposed work of breathing. In the beginning, the amount of pressure support should deliver a full tidal volume breath (PS_{max}) and with further improvement in spontaneous breathing, the PSV support can be reduced sequentially until a tidal volume of 3 to 4 mL/kg is reached (PS_{min}). Most babies can be extubated from this level of support if they are showing regular respiratory drive.

In VG, the initial ventilation is started in the synchronized intermittent positive pressure ventilation (SIPPV) mode with a trigger sensitivity set at 1. This may need subsequent adjustment to reduce the effect of leak-induced auto-triggering. The starting tidal volume reference range is 4 to 6 mL/kg, which can be adjusted based on blood gas analyses. It takes between six and eight breaths to reach the targeted tidal volume; the exact number depends upon the respiratory rate. If the PIP being used to deliver the desired tidal volume is several cm H_2O below PINSP (where PINSP is the maximum allowed pressure), then the set PINSP may be left as is. This extra available peak pressure can be used by the ventilator if lung compliance decreases (or resistance increases, endotracheal tube leak increases, or respiratory effort decreases). If the PIP used by the ventilator is close to or equal to the set PINSP, the set PINSP should be increased by at least 4 to 5 cm H_2O. This allows the ventilator some leeway to deliver the desired tidal volume in the event that compliance decreases. Once appropriate levels of tidal volume have been established, weaning should be an "automatic" process, with the amount of pressure deployed by the ventilator to provide the set tidal volume decreasing as the infant recovers. When the peak airway pressure used is very low, the infant may be ready for extubation.[46]

TABLE 44–3 Suggested Methods for Using Volume-Controlled Ventilation

Initial Mode	Start in volume-assist control mode. Adjust volume at the machine to deliver 4 to 6 mL/kg (measured at proximal endotracheal tube).
Time limit (A/C)	Use flow to adjust inspiratory time to 0.25 to 0.4 second.
Target ABG range	pH: 7.25 to 7.4 P_{CO_2}: 40 to 60 mm Hg P_{O_2}: 50 to 80 mm Hg
Weaning	Wean by reducing volume as tolerated but continue in A/C with control rate to ensure normocapnia and tidal volume delivery at 4 to 6 mL/kg. Switch to SIMV/PS when control rate is less than 30 breaths/min. Load with a methylxanthine.
Weaning to extubation	Decrease SIMV rate to 10 to 20 breaths/min. Decrease pressure support to maintain tidal volume at 3 to 4 mL/kg.
Trial of extubation	Consider when pressure has been weaned to provide 3 to 4 mL/kg tidal volume and baby is breathing spontaneously at low rate SIMV.

ABG, arterial blood gas; A/C, assist/control; SIMV, synchronized intermittent mandatory ventilation.

WEANING INFANTS FROM ASSISTED VENTILATION

Weaning is the process in which the work of breathing is shifted from the ventilator to the patient (see Box 44-9). Signs that an infant is ready to be weaned include improved gas exchange, more spontaneous breathing, and greater assumption of the work of breathing by the baby.[29] The most common reason for failure to wean is failure to wean!

There are physiologic requisites for weaning. First, the baby must have adequate spontaneous drive to sustain alveolar ventilation. This can be assessed by observation (how easily the baby appears to be breathing), and measurement of

BOX 44–9 Weaning from Assisted Ventilation

PHYSIOLOGIC REQUISITES

- Adequate spontaneous drive
- Overcome respiratory system load

ELEMENTS OF WEANING

- Maintenance of alveolar ventilation
  - Tidal volume
  - Frequency
- Assumption of work of breathing
- Nutritional aspects

IMPEDIMENTS TO WEANING

- Infection
- Neurologic/neuromuscular dysfunction
- Electrolyte imbalance
- Metabolic alkalosis
- Congestive heart failure
- Anemia
- Sedatives/analgesics
- Nutrition (inadequate calories or excessive non-nitrogen calories)

tidal volume and frequency, and thus calculation (or measurement) of minute ventilation. Second, the baby must be able to overcome the respiratory system load, which can be defined as the forces necessary to overcome the elastic and resistive properties of the lungs and airways.[29] In addition, there are defined elements of weaning (see Box 44-9). Tidal volume determinants include amplitude, inspiratory time gas flow rate, and pulmonary compliance. Frequency determinants include chemoreceptor function, and carbon dioxide production, as well as acid-base balance. Minute ventilation is determined by the product of tidal volume and frequency, and both spontaneous and mechanical components need to be evaluated. The work of breathing refers to the force or pressure necessary to overcome those forces that oppose gas flow and expansion of the lung during inspiration. It may be estimated by the product of pressure and volume or graphically as the integral of the pressure-volume loop; it is thus proportional to compliance, but it may also be elevated if there is increased resistance. It is an indirect measurement of energy expenditure or oxygen consumption. Finally, there are nutritional aspects. Adequate calories need to be provided to fuel the work of breathing and avoid catabolism. However, an excess of nonnitrogen calories may increase carbon dioxide production and impede weaning.[75]

Clinicians should also recognize impediments to successful weaning (see Box 44-9). These should be avoided or treated, if present, to provide the best possible chance for the baby to be successfully weaned and extubated. Adjunctive therapies, including corticosteroids, diuretics, and bronchodilators are often used to facilitate weaning, but only methylxanthines have sufficient evidence to be recommended.[5,43]

Weaning Strategies

Because infants are placed on assisted ventilation for differing reasons and because different primary strategies are used for the different causes of respiratory failure, it is nearly impossible to design a “one size fits all” strategy. It has become even more confusing in the era of patient-triggered ventilation. In earlier times, when IMV was the only available mode, the usual strategy was to sequentially lower the rate and allow the baby to assume a greater burden of gas exchange by spontaneous breathing. During triggered ventilation, as long as the baby breathes above the control rate, lowering the ventilator rate has no effect on gas exchange.

In general, it is probably best to reduce the potentially most harmful parameter first. With the exception of HFOV, it is best to limit changes to one parameter at a time to better assess its impact on the baby’s respiratory status. Avoid changes of a large magnitude, and be sure to document the baby’s responses to changes, so that subsequent care providers can continue or adjust the plan.

Weaning and Ventilator Modes

For A/C ventilation, the primary strategy should be to decrease the PIP. The PIP should be adjusted to keep tidal volume and P_{CO_2} in a reasonable range. If it is reduced too much, and if alveolar ventilation is inadequate, it is reflected by an increase in the spontaneous (and hence, mechanical) ventilator rate. It has also been suggested that increasing the assist sensitivity to increase the patient effort to trigger might be an alternative method, but there are no data to date to support this. Babies may be extubated directly from A/C, or they may be switched to SIMV or low rate SIMV with PS.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION

The goal of weaning in SIMV is to maintain minute ventilation while reducing the level of mechanical support. This can be accomplished by reductions in either the PIP or the SIMV rate, using the spontaneous rate as the monitored variable. As the SIMV rate is lowered, the baby may require additional support of spontaneous breathing to overcome the imposed work of breathing, either by increasing the PEEP, flow rate, or inspiratory time, or by adding PSV.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION AND PRESSURE SUPPORT VENTILATION

The combined use of SIMV and PSV is analogous to A/C ventilation, except that changes can be made independently. Physiologic studies have demonstrated that if spontaneous breaths are fully supported with PSV (sufficient pressure to deliver a full tidal volume breath), lower SIMV rates can be used and weaning is faster.[40] In addition, the PSV breaths are fully synchronized because they are patient-triggered and flow-cycled. If babies demonstrate reliable respiratory drive, PSV can even be used alone as a weaning strategy, with extubation occurring when the delivered tidal volumes are in the 3- to 5-mL/kg range.

ASSESSMENT FOR EXTUBATION

In the past, predictive indices, such as blood gas or pulmonary mechanics testing, have not been adequately sensitive or specific in assessing readiness for extubation.[3,67] Part of the problem is not knowing what will happen to the airway once the endotracheal tube is removed, and obstructive apnea is common. More recently, attention to spontaneous breathing while receiving only endotracheal CPAP has been shown to have a high positive predictive value for successful extubation. This can be accomplished by examining the relationship of spontaneous to mechanical ventilation,[36,77] or simply by observing patient stability during a 10-minute period of CPAP.[44]

Postextubation Care

The care of the infant after extubation usually reflects clinician or institution preference. Most infants are extubated and placed on some form of continuous pressure provided by either nasal CPAP or nasal cannula, with or without supplemental oxygen. Most clinical trials support the use of CPAP to avoid postextubation failure.[18] Prone positioning has also been shown to improve gas exchange, perhaps by stabilizing the chest wall and allowing abdominal viscera to fall away from the diaphragm. Postextubation stridor is a relatively common occurrence from narrowing of the upper airway from swelling. It is usually transient, but it may require reintubation. Some affected infants benefit from inhalational sympathomimetics or a short course of corticosteroids.

HIGH-FREQUENCY VENTILATION

HFV refers to a form of assisted ventilation in which the delivered gas volumes are less than the anatomic dead space volume and are provided to the patient at very rapid rates. During HFV, carbon dioxide removal is the product of frequency and the square of the tidal volume, and thus the pressure required to set the amplitude can be considerably less than that used during conventional mechanical (tidal) ventilation (CMV). In addition, because the inspiratory times are much shorter, the duration of positive pressure is less and the alveoli are potentially exposed to less barotrauma. Because carbon dioxide removal can be achieved at lower amplitudes compared to conventional ventilation, HFV allows the clinician to use a higher PEEP with a wider degree of safety.[8] The two most commonly used forms of HFV are high-frequency jet ventilation (HFJV) and high-frequency oscillatory ventilation (HFOV) (Table 44-4).

HFV has been used to treat lung conditions that have been challenging for CMV, including air leaks, refractory hypoxemia, and respiratory insufficiency after cardiac surgery. It also differs from CMV in not trying to mimic normal spontaneous breathing, and because of its unique flow characteristics, it provides a different pattern of gas distribution within the lungs, where airway resistance, and not compliance, is the major determinant of gas distribution. Because gas flow is more rapid during HFV than during CMV, the gas flow profile is more laminar or parabolic. Thus inspiratory gas tends to remain in the center of the airways, enabling it to penetrate more deeply into the lung and to bypass airway disruptions, such as bronchopleural or tracheoesophageal fistulas,[30] or other thoracic air leaks, such as pneumothorax or pulmonary interstitial emphysema.[48]

Although the basic principles of mechanical ventilation are essentially the same for HFV as for CMV, HFV enables better uncoupling of oxygenation and ventilation. During CMV, adjustments made to improve oxygenation often adversely affect ventilation, and vice versa. This phenomenon is much less apparent during HFV, particularly during oscillatory ventilation.

Although both HFJV and HFOV have been in use for more than 20 years, there is a relative paucity of evidence for either modality. A recent thorough review by Lampland and Mammel summarizes the clinical evidence to date.[50]

TABLE 44–4 Characteristics of High-Frequency Ventilation

	High-Frequency Jet Ventilation	High-Frequency Oscillatory Ventilation
Rate	360 to 450 breaths/min	480 to 900 breaths/min
Inspiratory time	20 msec	10 to 20 msec
Exhalation	Passive	Active
Tandem CMV	Yes	No
Gas delivery	High-velocity injector	Piston

High-Frequency Jet Ventilation

HFJV involves pulses of high-velocity gas injected directly into the upper airway, either by a special endotracheal tube adapter (proximally) or a specialized triple lumen endotracheal tube (distally). It is used in tandem with a conventional ventilator, which provides PEEP and can be used to deliver “sigh” breaths and maintain lung expansion.

HFJV is similar to CMV in that inspiration is active and expiration is passive, meaning that exhaled gas flow results from the elastic recoil of the lungs. Theories of gas exchange during HFJV suggest that there may be some facilitation of expiratory gas flow by countercurrent energy imparted by the inspiratory flow. HFJV rates range from 240 to 660 breaths/min, and most commonly rates of 360 to 450 are used in clinical practice. Inspiratory time is usually set at 0.02 second (20 msec). Gas volumes delivered during HFJV are considerably smaller than those delivered during CMV.[47]

Different strategies for using HFJV have been proposed for different diseases. A “low-pressure” strategy is adopted for conditions in which air leak is the predominant pathophysiology. Here, the use of lower PIP allows for healing. If oxygenation is problematic, higher PEEP or more CMV support can be offered. The “optimal volume” strategy is used for conditions in which there is a tendency for the alveoli to collapse, such as RDS. HFJV is used to optimize the lung volume and improve ventilation/perfusion matching. Clinicians must be aware that because two ventilators are being used, there are usually two oxygen blenders, and both must be adjusted when a change in the fraction of inspired oxygen is made.

Clinical experience has demonstrated that HFJV is superior to rapid rate IMV in the management of preterm infants with pulmonary interstitial emphysema.[48] HFJV has also been used to treat other types of intractable air leaks, such as esophageal atresia/tracheoesophageal fistula complicated by RDS.[30] One trial comparing HFJV with IMV for the early management of RDS showed less oxygen dependency at discharge when HFJV was used.[49]

High-Frequency Oscillatory Ventilation

HFOV is another form of HFV. Its major distinguishing feature is the addition of active exhalation, whereby removal of exhaled gas is facilitated by negative pressure applied during expiration. Typical rates vary between 8 and 15 Hz (480 and 900 breaths/min). Depending upon the nature of the device, I/E ratios vary from 1:1 to 1:2, and the clinical implication is that inspiratory times and tidal volumes are very short and small, respectively.

The general principles of mechanical ventilation also apply to the oscillator. Mean Paw is used to inflate the lung and recruit alveoli for oxygenation. This may be thought of as continuous distending pressure, in that the lung remains inflated throughout the respiratory cycle. Ventilation is accomplished by adjusting the amplitude, which in turn regulates gas delivery during inspiration and gas removal during expiration.

HFOV has been used both as a primary device for the initial treatment of respiratory failure, and as a rescue strategy for infants who fail to respond to CMV. Some centers prefer to wean and extubate directly from HFOV, whereas others prefer to transition to and wean from CMV. HFOV appears to be the best way to deliver inhaled nitric oxide because of its ability to recruit lung volume and match ventilation and perfusion.

The major drawback to HFOV is the inability to monitor the baby as closely as is possible with CMV. Proper settings are verified by blood gases, the degree of lung expansion on the chest radiograph, and by an assessment of chest wall movement during HFOV, referred to as the “chest wiggle factor.” Because intrathoracic pressure can be high, close attention needs to be paid to cardiac output and perfusion. In addition, care must be taken to avoid gas trapping in babies requiring a high amplitude for adequate ventilation, which can result in the collapse of the smaller airways, described as “choke points,” during active exhalation.[15]

MONITORING OF VENTILATED INFANTS

Babies requiring assisted ventilation require close monitoring to assess underlying lung pathology, response to treatment, and surveillance for associated complications. Monitoring may be considered in five broad categories: (1) clinical evaluation, (2) assessment of gas exchange, (3) chest imaging, (4) pulmonary function and pulmonary mechanics testing, and (5) extrapulmonary monitoring to screen for complications known to contribute to neonatal mortality and morbidity.

Clinical Evaluation

Clinical examination of the cardiorespiratory system includes observations for general physical condition, chest wall movement, equality of air entry, and the presence of abnormal sounds such as rales, rhonchi, or heart murmurs. The clinician must evaluate the interaction between positive pressure ventilation and the baby’s spontaneous breaths to detect dyssynchrony, which can interfere with gas exchange and lead to gas trapping and air leaks. Rapid shallow breathing and the presence of subcostal/intercostal retractions in ventilated babies may suggest air hunger or increased work of breathing, which can be corrected by adjustments of ventilator parameters. A hyperactive precordium, tachycardia, easily felt peripheral pulses, and the presence of a cardiac murmur appearing on day 2 or 3 suggest a left-to-right shunt through a patent ductus arteriosus (PDA). In contrast, right-to-left shunting causing cyanosis (and desaturation on pulse oximetry) suggests persistent pulmonary hypertension of the newborn. Assessment of cardiac function, blood pressure, and tissue perfusion is an important part of evaluation because these directly affect respiratory status. Blood pressure measurements should be interpreted in conjunction with other indices of tissue perfusion, such as capillary refill time, acid-base status, urinary output, and echocardiographic evaluation of myocardial contractility and cardiac output. Bedside transillumination by a bright fiberoptic light source applied to the chest wall is a useful and effective way to detect pneumothorax, pneumomediastinum, and pneumopericardium, which may require urgent attention. Other systemic clinical evaluation includes examination of abdomen for tenderness or distention and an assessment of the neurologic status by assessing tone, posture, and movement.

Assessment of Gas Exchange

BLOOD GASES AND ACID-BASE BALANCE

Clinical interpretation of blood gases alone conveys relatively little information and must be interpreted in a clinical context, taking into account factors such as the work of breathing, recent trends, and the stage of illness. For example, a $Pa\text{CO}_2$ of 65 mm Hg is a genuine source of concern in an infant in the first few hours of life but may be perfectly acceptable in an infant on long-term ventilation for bronchopulmonary dysplasia (BPD). There is also a wide range of “normal” blood gas values, depending upon gestational age, postnatal age, source (arterial, venous, or capillary), and disease state. In most infants with respiratory disease, the goal is not to make blood gases entirely normal, but to keep them within a target range appropriate for the clinical status.

Analysis of gas exchange also requires an understanding of respiratory physiology. Oxygenation is dependent on ventilation-perfusion matching, whereas movement of CO_2 from the blood into the alveoli is dependent on alveolar ventilation (the product of alveolar tidal volume and respiratory rate). The pH of arterial blood is determined primarily by $Pa\text{CO}_2$, lactic acid (produced by anaerobic metabolism), and buffering capacity, particularly serum or plasma bicarbonate and plasma hemoglobin concentration.

Arterial blood gases remain the gold standard for assessment, but analysis can only be performed intermittently. Moreover, arterial catheters are invasive and intermittent arterial sampling requires skill and is painful for the patient. These limitations have led to increasing acceptance of noninvasive techniques, such as transcutaneous oxygen monitoring ($TcPO_2$) and oxygen saturation monitoring using pulse oximetry. There are no data to show that any one method is superior. A $TcPO_2$ value of more than 80 mmHg is associated with a higher incidence of retinopathy of prematurity. A correlation between $TcPO_2$ and pulse oximetry (SpO_2) showed that oxygen saturation above 92% carries a risk of hyperoxia and thus an increased risk of ROP in preterm babies receiving supplemental oxygen.[66] One disadvantage of pulse oximetry is that it is not reliable in cases of severe hypotension or marked edema. Pulse oximeters measure either functional saturation or fractional saturation, which are device-specific. Before interpreting an SpO_2 reading, the quality of signal should be assessed by observing the accompanying arterial pulse waveform. (See part 2)

The ventilatory parameters that affect oxygenation include $Fi\text{O}_2$, PIP, PEEP, inspiratory time, tidal volume, and flow rate. Persistent hypoxemia despite appropriate adjustments in ventilatory parameters may indicate inadequate pulmonary bloodflow or perfusion, or right-to-left shunting. Another important factor which affects arterial oxygen tension is altitude and this is relevant to air transport of sick babies.

Transcutaneous partial pressure of carbon dioxide ($TcPCO_2$) can be measured noninvasively and continuously using a special skin electrode. One of the factors influencing measurements is sensor temperature, which is optimal at 42°C. If $TcPCO_2$ is used in combination with a $TcPCO_2$ sensor, a sensor temperature of 44°C can be used without jeopardizing the precision of the $TcPCO_2$ measurement. $TcPCO_2$ measurements are relatively independent of sensor site and skin thickness. $TcPCO_2$ may be falsely high in severe shock and its precision may be affected if $Paco_2$ is more than 45 mmHg or if arterial pH is less than 7.30, but there is no systemic overestimation or underestimation of $Paco_2$ under these conditions. Sensitivity of $TcPCO_2$ in detecting hypercapnia and hypocapnia is 80% to 90%.

Base Deficit

In the healthy term infant, the base deficit is usually 3 to 5 mEq/L. However, base deficit can vary significantly. In patients with a base deficit between 5 and 10 mEq/L, assuming reasonable tissue perfusion, no acute intervention is generally needed. However, a base deficit greater than 10 mEq/L should prompt a careful assessment of the infant for evidence of hypoperfusion. In most cases, correcting the underlying cause of metabolic acidosis is far more effective and less dangerous than administering sodium bicarbonate.

Capnometry or End-Tidal Carbon Dioxide Monitoring

$ETCO_2$ is an alternative method of measuring carbon dioxide and is called capnometry. Depending on the gas sampling technique, devices are either mainstream or sidestream capnometers. Capnometry measurements are less reliable than $TCPCO_2$ monitoring especially when the ventilation/perfusion relationship is not uniform within the lungs, as in infants with RDS or persistent pulmonary hypertension of the newborn.

Partial pressure of CO_2 is affected by minute ventilation, which in turn is the product of tidal volume and frequency during CMV. Of these two parameters, adjustment in tidal volume (by adjusting the amplitude) has a more predictable effect on minute ventilation changes.

Radiography and Other Chest Imaging

Chest radiography is the most commonly used imaging modality on neonatal intensive care units, both for diagnosing and following the course of a disease process. However, the specificity of chest radiography is poor and should always be interpreted in context with clinical information. The findings on chest radiographs are mostly suggestive of pathology and are not always diagnostic.

Ultrasound is a very popular imaging modality because of its portability and scope of repeated examination without any ionizing radiation. Although use of ultrasound for diagnosis of primary respiratory disorders is limited, it can be used to evaluate diaphragmatic excursion and position in suspected cases of phrenic nerve paresis or paralysis. Computed tomography and magnetic resonance imaging have limited use in neonatal intensive care units because of practical difficulties but are helpful in certain conditions such as congenital cystic adenomatoid malformation, pulmonary sequestration, or complex congenital heart disease when there is insufficient information from echocardiography (e.g., total anomalous pulmonary venous return). Color Doppler echocardiography is now routinely used for assessment of cardiac function and hemodynamic assessment, which may impact the respiratory status in ventilated infants.

Real-Time Pulmonary Graphic Monitoring

Real-time graphic analysis of pulmonary mechanics in infants receiving assisted ventilation has emerged as a valuable tool to aid clinical decision making. A working knowledge of pulmonary mechanics also improves understanding of pulmonary physiology and pathophysiology. Pulmonary mechanics monitoring consists of measurements of several parameters, which define different aspects of lung function. Specifically, clinicians are interested in the *pressure* necessary to cause a *flow* of gas to enter the airway and increase the *volume* of the lungs. From these variables, several other measures of pulmonary mechanics can also be derived, such as pulmonary *compliance* (Fig. 44-40) and *resistance*, and resistive work of breathing (energetics). From this information, displayed as either numerical values or graphic representations, useful information can be obtained and used for diagnosing specific lung pathology, evaluating the disease progression, and determining therapeutic interventions. Besides assessment of acute respiratory distress and evaluation of mechanical ventilation, other potential benefits of pulmonary graphics include assessment of suitability for weaning and the objective determination of the efficacy of pharmacologic treatments. (See Part 2.)

The two representations of pulmonary graphics most commonly used in clinical practice are waveforms and loops. Both patterns display the relationships between pressure, volume, flow, and time.

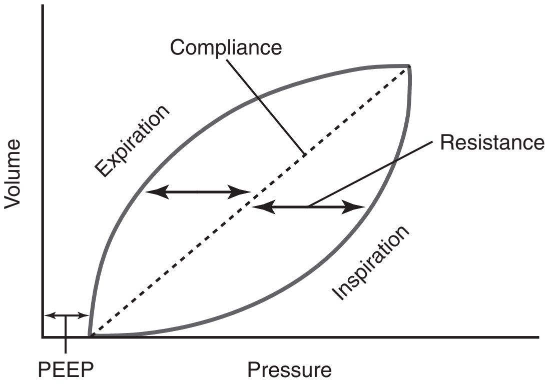

Figure 44–40. Schematic representation of a pressure-volume loop denoting the relationship of pressure, volume, and time.

VOLUME AND PRESSURE WAVEFORMS

Measurement of tidal volume is becoming increasingly important in ventilatory management. The desired inspiratory tidal volume for a ventilated breath ranges from 4 to 7 mL/kg; for spontaneous breaths, a tidal volume of 3 to 4 mL/kg generally indicates suitability for weaning or extubating. Minute ventilation (tidal volume × frequency) is another predictor of weaning, especially in small infants who have short inspiratory times and a higher frequency. Normal values are generally between 240 and 360 mL/kg/min. Breath-to-breath variability and longer term trends are useful in selecting the mode and modality of ventilation and designing individualized strategies based on pulmonary pathophysiology.

FLOW WAVEFORM

Flow is the volume of gas delivered per unit of time. Inspiratory flow is plotted above (positive) and expiratory flow is plotted below the abscissa (negative). The duration and shape of the inspiratory and expiratory flow waveforms are affected by many factors including type of ventilation, I/E ratio, impedance and resistance to gas flow (Fig. 44-41), and the effect of therapeutic agents, such as bronchodilators. The flow waveform can be used to determine if gas trapping is present (Fig. 44-42).

PULMONARY MECHANICS (LOOPS)

Loops are commonly used to demonstrate correlations between airway pressure and volume, and airflow and lung volume. Pressure-volume (P-V) loops graphically depict the correlation between the ventilator inspiratory pressure and the volume of gas entering the lungs on a breath-to-breath basis. A line connecting the points of zero flow (the changeover from expiration to inspiration) is the compliance axis and the slope of this line reflects pulmonary compliance (a measure of the change in volume per unit of added pressure). An estimate of compliance can be made by looking at the slope of the compliance axis; a 45-degree slope indicates a compliance of 1.0. If this slope is more toward vertical, compliance is improving, and conversely, if the axis moves nearer to horizontal, compliance is decreasing. (See also Part 2 of this chapter.)

Increased resistance, as is seen in conditions like meconium aspiration syndrome and BPD, causes a bowing around the compliance line, and is an indirect measure of the work of breathing, which can be estimated by the P-V loop and the area to its left, as measured from the highest point. The P-V loop may also be used to determine the optimal PEEP. Pressure-volume loops that appear "boxlike" indicate the need for a higher opening pressure, and the shape can be normalized by increasing the PEEP and PIP. Another potentially dangerous condition, lung hyperinflation, can also be detected graphically (Fig. 44-43).

Another valuable measurement is resistance. This can be assessed by observing the flow-volume (F-V) loop, which graphically displays the relation between change in volume and change in airflow (Fig. 44-44). A normal flow volume loop should be rounded or oval and should appear symmetrical with respect to the abscissa. Identification and measurement of endotracheal tube leak is possible with graphic monitoring. Increased resistance, and turbulent gas flow from excessive condensation in the ventilator circuit or secretions in the airway can also be identified by the appearance of a noisy flow signal.

Graphic monitoring is largely pattern recognition and should be used to trend data. Appropriate scaling of axes is crucial to proper interpretation. However, if properly calibrated, the real-time breath-to-breath view of pulmonary mechanics and respiratory waveforms allows the clinicians to fine-tune ventilator settings and provides constant surveillance

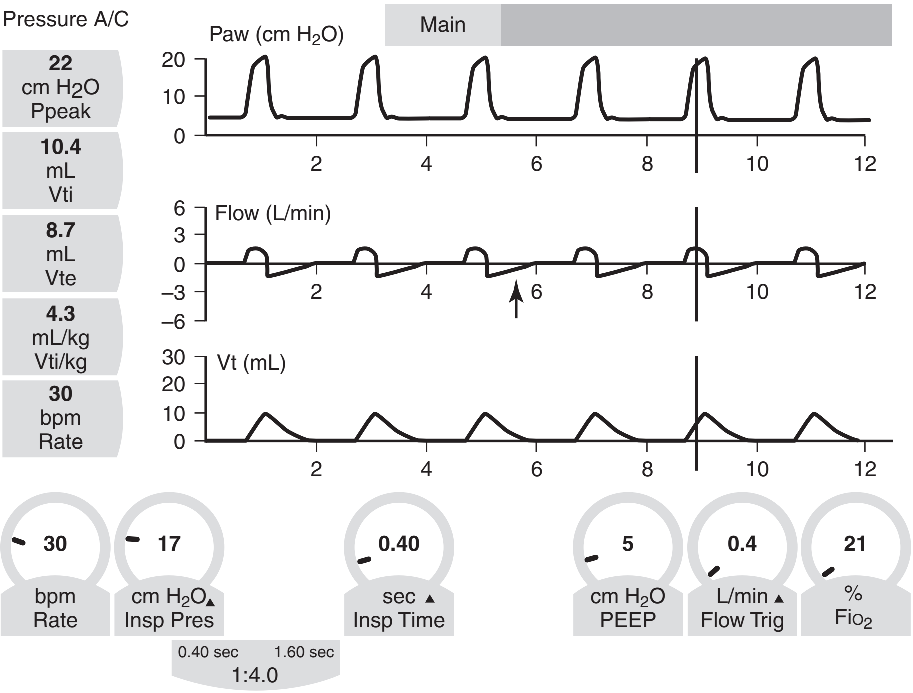

Figure 44–41. Flow waveform center tracing demonstrating high expiratory resistance. Note the decreased peak expiratory flow and the prolonged time to return to baseline (*arrow*).

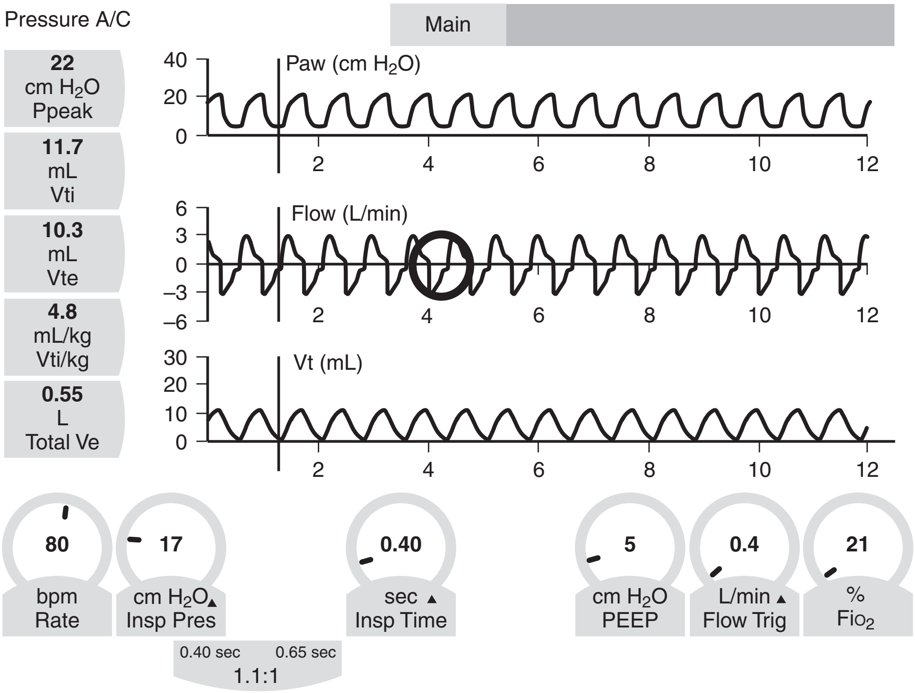

Figure 44–42. Flow waveform showing gas trapping *(circle)*. Note that the expiratory portion of the flow waveform fails to reach the baseline (zero flow state) before the next breath is initiated.

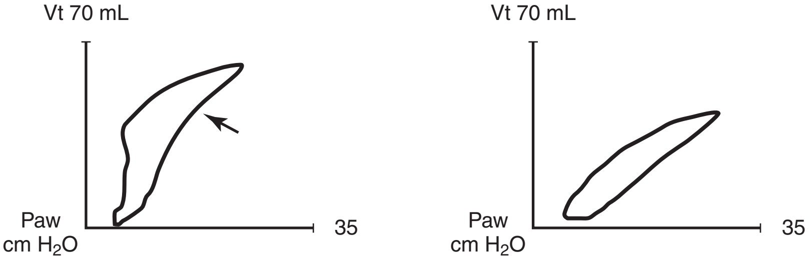

Figure 44–43. Pressure-volume loops. The loop on the left shows hyperinflation. Note the upper inflection point *(arrow)*. Above this point, incremental pressure is producing less change in lung volume per unit pressure than below it. On the right, peak inspiratory pressure has been reduced and the loop shows normal hysteresis.

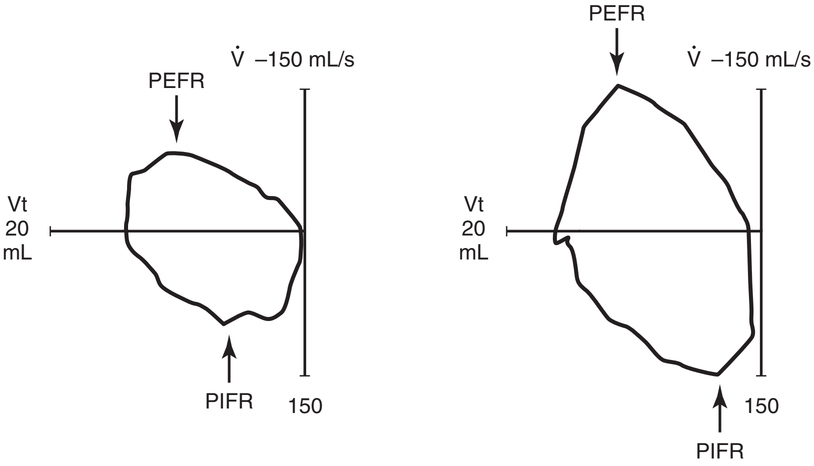

Figure 44–44. Flow-volume loops. On the left, increased resistance produces a smaller loop, with decreased peak inspiratory flow rates (PIFR) and peak expiratory flow rates (PEFR), denoted by *arrows*. On the right, successful treatment with a bronchodilator decreased resistance and improved both PIFR and PEFR.

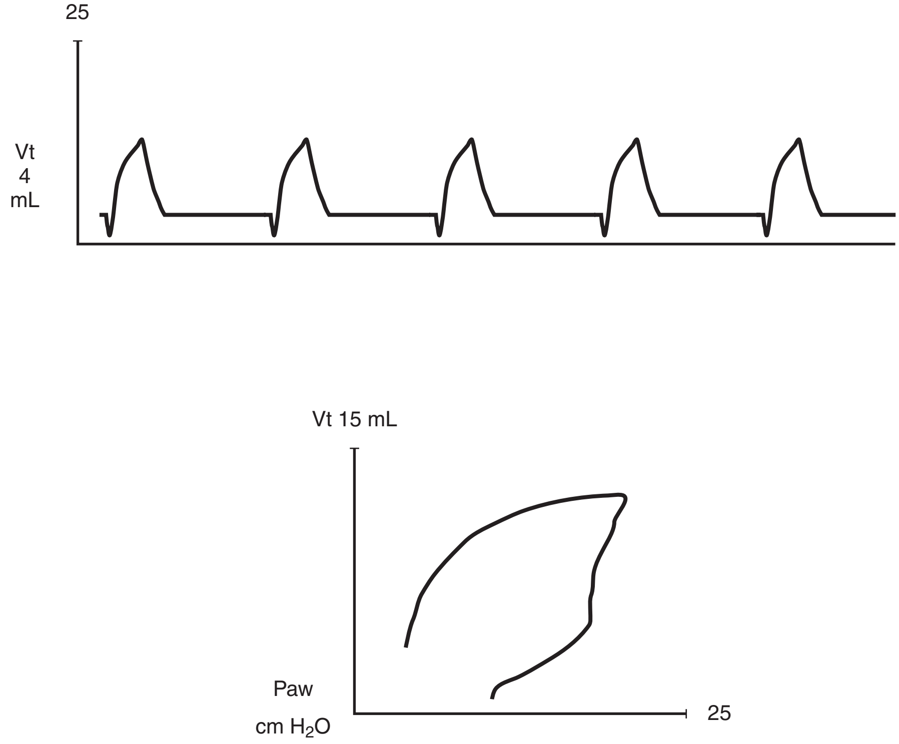

Figure 44–45. Large endotracheal tube leak. Note that the pressure-volume loop (bottom) fails to close, and the volume waveform fails to reach zero (top).

for many potential complications such as gas trapping and lung overdistention before they become clinically apparent. Endotracheal tube leaks may also be detected graphically (Fig. 44-45).

COMPLICATIONS OF ASSISTED VENTILATION

See Box 44-10.

Airway

Placement of an endotracheal tube into the airway can potentially damage the mucosal and submucosal tissues causing injury which can obstruct gas exchange, lead to other functional disabilities, and create cosmetic deformities. Some of these are idiosyncratic, while others relate to the duration of ventilation, frequency of intubations, and associated complications such as infection.

UPPER AIRWAY

Procedural complications of endotracheal intubation are generally traumatic in nature and result from mechanical damage to structures in the nasopharynx or oropharynx, trachea, and larynx. These injuries include superficial mucosal erosion, damage to the alveolar ridge (with subsequent dental problems),[54] perforation of the esophagus[65] or trachea,[69] injury to the vocal cords,[78] and injury related to fixation devices such as tape. Long-term nasotracheal intubation may cause erosion of the nasal septum and nasal deformities.[38] Acquired palatal grooves[33] and even cleft palate[32] have been described after long-term orotracheal intubation.

TRACHEA

Less serious problems, which tend to resolve spontaneously over time, include tracheal and laryngeal mucosal metaplasia, subglottic cysts, tracheal enlargement, and tracheobronchomalacia. Subglottic stenosis is a life-threatening condition generally requiring tracheostomy. Its etiology is still not completely understood, but associations have been demonstrated for duration of intubation, number of intubations, and the degree of prematurity.[71] Necrotizing tracheobronchitis was another highly lethal acquired entity.[7] This disorder was seen most commonly in the early days of HFJV and was thought to be related to the effects of insufficient humidification of inspired gas. It has all but disappeared since refinements were made in humidification systems.

Lungs

VENTILATOR-ASSOCIATED PNEUMONIA

Ventilator-associated pneumonia (VAP) is a disease entity defined as pneumonia characterized by the presence of new and persistent focal radiographic infiltrates in a ventilated infant appearing more than 48 hours after admission to the neonatal intensive care unit. (See Part 4.)

VAP is a commonly observed complication in babies requiring mechanical ventilation. It results from either dissemination of microorganisms from colonized mucosal sites or aspiration of gastric contents. Repeated and prolonged endotracheal intubation, as well as suctioning, can disrupt mucosal integrity and promote dissemination. Occasionally microorganisms may be transmitted from contaminated equipment. The reported incidence of VAP is 6.5 cases per 1000 ventilator days. A number of risk factors and associations have been identified, including prematurity; use of corticosteroids, H2 blockers, antacids, and proton pump inhibitors; overcrowding, understaffing; and inadequate disinfection of equipment.

VAP should be suspected in a ventilated infant if there is deterioration in the respiratory status unexplained by other events or conditions. Blood cultures may or may not be positive in infants with VAP. Sepsis and pneumonia should also be considered when there is unexplained temperature instability, hyperglycemia, hypoglycemia, acidosis, feeding intolerance, or abdominal distention. Radiographic findings are nonspecific and may be difficult to distinguish from chronic lung disease in the older baby. Bacterial and fungal pathogens are the most common agents. Tracheal aspirates for culture are not helpful in diagnosis of pneumonia and may merely reflect colonization. Laboratory investigations, such as abnormal blood counts and elevated acute phase reactants, such as C-reactive protein, suggest the diagnosis of sepsis or pneumonia.[58]

Management of VAP includes broad-spectrum antibacterial or antifungal agents, hemodynamic support, and provision of adequate nutrition. Respiratory support should be maintained as necessary. If hypoxemia is refractory despite maximal ventilatory support, consideration should be given to use of inhaled nitric oxide or extracorporeal membrane oxygenation for term and late preterm infants, if they meet criteria. Benefit from the use of additional surfactant is unproven but anecdotal reports suggest efficacy with preparations that contain surfactant proteins A and D. A recent study by Aly and associates suggests that more frequent positioning of babies on their sides, as opposed to supine, may decrease the incidence of VAP.[1]

BOX 44–10 Complications of Assisted Ventilation

AIRWAY

- Upper airway
  - Trauma
  - Abnormal dentition
  - Esophageal perforation
  - Nasal septal injury (nasotracheal tubes)
  - Acquired palatal groove (orotracheal tubes)
- Trachea
  - Tracheal and laryngeal mucosal metaplasma
  - Subglottic cysts
  - Tracheal enlargement
  - Tracheobronchomalacia
  - Tracheal perforation
  - Vocal cord paralysis/paresis
  - Subglottic stenosis
  - Necrotizing tracheobronchitis

LUNGS

- Ventilator-associated pneumonia
- Air leaks
  - Pneumomediastinum
  - Pneumothorax
  - Subcutaneous emphysema
  - Pulmonary interstitial emphysema
  - Pneumopericardium
  - Pneumoperitoneum (transdiaphragmatic)
- Ventilator induced lung injury
- Chronic lung disease/bronchopulmonary dysplasia

MISCELLANEOUS

- Imposed work of breathing
- Patent ductus arteriosus

NEUROLOGIC

- Intraventricular hemorrhage
- Periventricular leukomalacia
- Retinopathy of prematurity

AIR LEAKS

Thoracic air leaks are collections of pulmonary gas residing outside the pulmonary airspaces. They include pneumothorax, pneumomediastinum, pneumopericardium, pulmonary interstitial emphysema (PIE), pneumoperitoneum, and subcutaneous emphysema. Pneumothorax often results from high inspiratory pressure and unevenly distributed ventilation. The ventilator parameters that are conducive to the development of pneumothorax include (1) a prolonged inspiratory time or an inversed I/E ratio, (2) high PIP or mean Paw, (3) high flow rates, and (4) patient-ventilator asynchrony. There is also higher incidence of pneumothorax in the presence of certain disease conditions such as meconium and other aspiration syndromes, cystic fibrosis, and pulmonary hypoplasia, which are characterized by uneven lung compliance and alveolar overdistention. (See Part 4.)

Pneumothorax in patients receiving positive pressure ventilation can manifest in three ways: (1) asymptomatic, where it is first detected on a routine chest radiograph without or with subtle clinical signs; (2) deterioration in laboratory or bedside monitoring findings, without an obvious change in the patient's clinical condition, but is suspected because of worsening blood gases and increasing ventilatory requirements; and (3) acute clinical deterioration with tension, which is the most common presentation in ventilated infants. Infants with tension pneumothorax present with agitation and increasing respiratory distress, hypotension, and other signs of cardiovascular collapse. Auscultation of the chest reveals diminished or absent breath sounds on the affected side, with a contralateral shift of heart sounds and the point of maximum impulse. Breath sounds on the contralateral side may also be decreased as tension worsens and compresses the unaffected lung. Arterial blood gases may show respiratory or mixed acidosis and hypoxemia. Transillumination reveals increased transmission of light on the involved side. Chest radiography is confirmatory. Tension pneumothorax is a medical emergency and requires prompt treatment. Needle aspiration (thoracentesis) can be used as a temporizing measure, but generally needs to be followed by placement of a chest tube (thoracostomy) for resolution. Smaller gas collections may resolve spontaneously without further intervention but are likely to recur with ongoing mechanical ventilation.

The incidence of pneumothorax has diminished over the years. This may be related to a number of factors including antenatal corticosteroid treatment, surfactant therapy, and the increased use of prenatal ultrasound, which has enabled the diagnosis of conditions like congenital diaphragmatic hernia/pulmonary hypoplasia with predisposition to pneumothorax. Various ventilatory strategies have also been employed to reduce the risks of air leak. Rapid rate IMV (more than 60 breaths/min) has been used to decrease inspiratory time and the duration of positive pressure (and hence tidal volume), and to produce less asynchronous breathing. However, rapid rate ventilation can also cause inadvertent PEEP and gas trapping. Synchronized ventilation, such as SIMV or A/C, may reduce the incidence of air leak by avoiding patient-ventilator asynchrony. The use of flow cycling enables complete synchronization, even during expiration. In rare instances, neuromuscular paralysis may be needed when a patient is actively "fighting" the ventilator despite adequate sedation.

Pulmonary interstitial emphysema often precedes the development of pneumothorax and can be localized or widespread throughout one or both lungs. It develops when the most compliant portion of the terminal airway ruptures, allowing gas to escape into the interstitial space. Gas may accumulate in the interstitium, compressing both the airway and adjacent alveoli. PIE alters pulmonary mechanics by decreasing compliance, increasing resistance, contributing to gas trapping, and increasing ventilation-perfusion mismatch. PIE also impedes pulmonary bloodflow. Diagnosis is based on the chest radiograph, which shows fine linear or radial radiolucencies. Unilateral PIE that is less severe may respond to decubitus positioning. Left-sided PIE may be alleviated by selective intubation of the right main bronchus if the infant can tolerate single lung ventilation. Management of generalized PIE should aim to reduce inspiratory time and pressure. An often used strategy is to increase the PEEP in an attempt to stent the airways and allow more complete emptying of the alveoli during expiration. Alternatively, HFJV has been shown to decrease time to resolution and to improve survival in infants with very low birthweight, compared with rapid rate IMV.[48]

Pneumomediastinum is usually of little clinical importance and usually does not need to be drained. However, its presence should alert the clinician of an increased risk for subsequent symptomatic air leaks. Symptomatic infants are often placed in 100% oxygen for up to 24 hours (nitrogen washout). Although this may make the infant more comfortable and potentially decrease the air leak, there is no evidence to support the practice.

Pneumopericardium occurs when air from the pleural space or mediastinum enters the pericardial sac through a defect that is often located at the reflection near the ostia of pulmonary veins. The diagnosis should be suspected from rapid clinical deterioration, which includes respiratory compromise and cardiovascular collapse, with a narrow pulse pressure and diminished perfusion. It can be diagnosed by transillumination and confirmed by radiography, which shows the air completely encircling the heart. Cardiac tamponade is a life-threatening event and requires immediate drainage. Needle aspiration (pericardiocentesis) via the subxiphoid route may be used to drain the air as a temporizing measure, but a pericardial drain is usually necessary. The majority of cases occur in infants ventilated with high PIP, high mean Paw, and long inspiratory time.

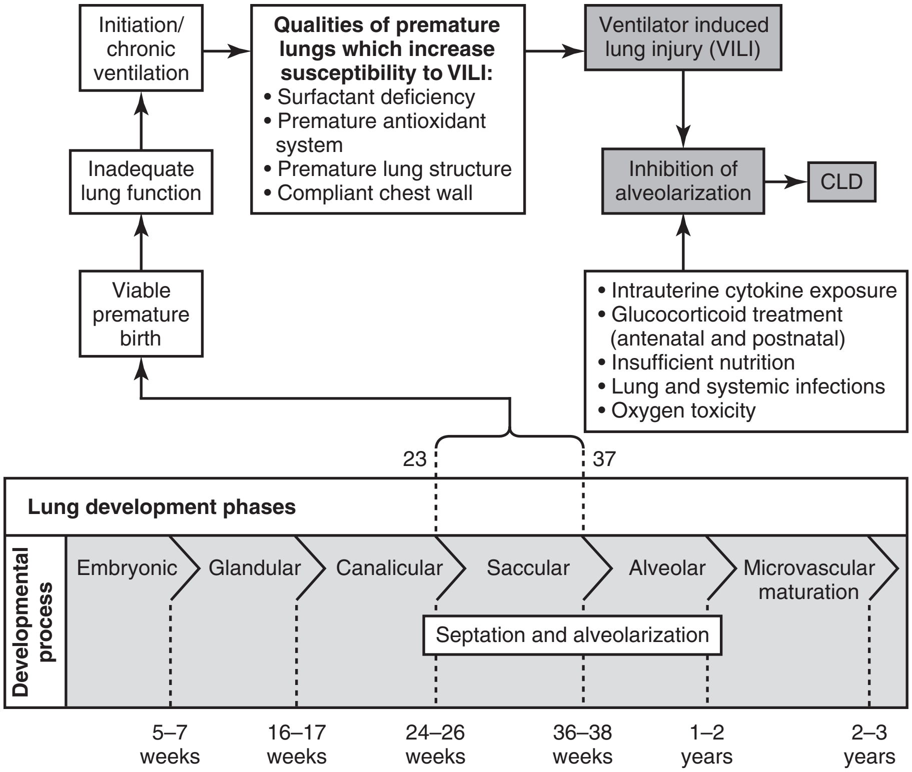
Pneumoperitoneum usually results from rupture or perforation of an abdominal viscus, but on rare occasions, gas from a thoracic leak can dissect transdiaphragmatically to an abdominal location. Recognition of this phenomenon can avoid an unnecessary laparotomy. A sample of the abdominal gas may be aspirated by abdominal paracentesis and analyzed for its oxygen concentration (if the baby is receiving more than room air). If the FiO_2 is greater than 0.21, the likely source is thoracic.

VENTILATOR-INDUCED LUNG INJURY

Despite the introduction of newer ventilatory techniques, which are based on sound physiologic principles, the incidence of chronic lung disease remains unacceptably high among babies who require mechanical ventilation, particularly for those born extremely prematurely. Chronic lung disease is multifactorial and involves a number of overlapping factors, such as prematurity, oxidant injury, inflammation, and injury related to mechanical ventilation, referred to as ventilator-induced lung injury (VILI).

Various terms, such as the pulmonary injury sequence, have been used to describe the individual components of VILI (Fig. 44-46); these are probably inter-related and likely to act synergistically to damage the developing lung as part of a pulmonary injury sequence.[2] *Barotrauma*, or excessive pressure, may disrupt airway epithelium and alveoli. *Volutrauma* refers to injury related to overdistention or stretching of the lung units by delivering too much gas. *Atelectrauma* refers to the damage caused by the repetitive opening and closing of the lung units (the cycle of recruitment and subsequent derecruitment). *Biotrauma* is a collective term to describe infection and inflammation, as well as the role of oxidative stress on the delicate tissue of the developing lung. *Rheotrauma* refers to damage evoked by inappropriate airway flow. If flow is excessive, inefficient gas exchange, inadvertent positive-end-expiratory pressure (PEEP), turbulence, and lung overinflation may occur. On the other hand, if flow is inadequate, it may lead to air hunger (flow starvation) and increased work of breathing. The cumulative effects of both endogenous and exogenous insults to the developing lung are a reduction in alveolarization and diminished pulmonary surface area capable of effective gas exchange.

With the introduction of newer techniques of mechanical ventilation in newborns, including pulmonary graphic monitoring, clinicians have now initiated strategies to avoid VILI. Monitoring of tidal volume delivery, irrespective of whether the target variable is volume or pressure, has become much more important in recent years. Indeed, delivering a physiologic tidal volume during conventional ventilation seems prudent. Of equal importance is the ability to customize ventilator settings to the specific needs of the patient.[28]



Initiation/ chronic ventilation
Qualities of premature lungs which increase susceptibility to VILI:
• Surfactant deficiency
• Premature antioxidant system
• Premature lung structure
• Compliant chest wall
Ventilator induced lung injury (VILI)
Inadequate lung function
Inhibition of alveolarization
CLD
Viable premature birth
• Intrauterine cytokine exposure
• Glucocorticoid treatment (antenatal and postnatal)
• Insufficient nutrition
• Lung and systemic infections
• Oxygen toxicity

CHRONIC LUNG DISEASE (BRONCHOPULMONARY DYSPLASIA)

See also Part 7.

Despite high use of antenatal steroids, surfactant replacement therapy, and newer ventilation techniques, chronic lung disease remains the major problem of neonatal intensive care. Bronchopulmonary dysplasia is a severe form of chronic lung disease and is characterized by presence of chronic respiratory insufficiency and a supplemental oxygen requirement, and an abnormal chest radiograph at 36 weeks' postmenstrual age. When Northway and colleagues originally described BPD in 1967, the affected infants ranged from 32 to 39 weeks' gestation and weighed 1474 to 3204 g at birth. Most had required high airway pressures and significant concentrations of supplemental oxygen. Their chest radiographs showed typical overinflation and cystic emphysema. A quarter of a century later, the demographics of BPD have changed. It occurs in more immature and very low birth weight babies who required only modest supplemental oxygen and ventilatory support. Their chest radiographs are also different and are characterized by diffuse haziness and a fine, lacy pattern. Infants with the "new" BPD do not seem to have had typical RDS, and many do not require ventilation during the first few days of life.[4]

Because BPD is associated with mechanical ventilation, some have advocated for the avoidance of assisted ventilation and the alternative use of noninvasive respiratory support such as NIPPV or NCPAP. This hypothesis is presently undergoing clinical evaluation. Attempts have also been made to use "gentler" ventilation by allowing "permissive hypercapnia" as a protective lung strategy.[51] The rationale for permissive hypercapnia is that by using less ventilation, there may be less volutrauma, a reduction of the duration of positive-pressure ventilation, and decreased alveolar ventilation. Whereas the secondary goals appear to be achievable, this approach has thus far failed to show a reduction in the incidence of BPD. In addition, it is very difficult to accomplish in the era of patient-triggered ventilation, because the baby with intact chemoreceptors increases his minute ventilation to try to achieve normocapnia.

There is compelling evidence that excessive tidal volume causes lung injury, so targeting tidal volume in a normal range (4 to 7 mL/kg) is gaining support within the neonatal community. In a recently published randomized clinical trial, babies receiving volume controlled ventilation were shown to have a trend toward reduction in chronic lung disease compared to those managed with pressure-limited ventilation.[65] A 20-month follow-up study of these infants also showed a reduced frequency of respiratory symptoms and need for treatment in the babies who had received volume-controlled ventilation.[64]

HFV is often used as an alternative to conventional ventilation and there is a large pool of data, both from animal and human studies, suggesting that this form of ventilation may have advantage over conventional tidal ventilation in reducing lung injury. However, the cumulative evidence from clinical trials does not show a reduction in CLD.[72]

Clinical investigation has not yet demonstrated a beneficial effect from any form of ventilation in preventing lung injury associated with mechanical ventilation. This may be the result of a number of other factors, including the underlying immaturity of the lung itself, which is more susceptible to the damaging effects of extrinsic factors.

MISCELLANEOUS COMPLICATIONS

Imposed Work of Breathing

Infants placed on mechanical ventilation assume additional burdens of breathing. First, there is an increase in airway resistance because of the placement of the narrow lumen endotracheal tube. Resistance to airflow is proportional to the fourth power of the radius of the tube and is linearly related to tube length. Second, there is an increase in dead space created by tubing and connectors. Finally, if a demand system is used, there is effort required to open the demand valve. Collectively, these have been referred to as the imposed work of breathing, primarily affecting spontaneous breaths taken by the baby between mechanical breaths. These spontaneous breaths are supported only by PEEP, unless the baby is receiving assist/control or pressure support ventilation, which was developed to overcome the imposed work of breathing and enhance patient comfort and endurance.

Patent Ductus Arteriosus

See also Chapter 45.

Patency of the ductus arteriosus (PDA) is a common problem in preterm infants. Its incidence varies inversely with gestational age and may be as high as 60% in infants less than 28 weeks' gestation. Its relationship to lung disease and mechanical ventilation is well established. Preterm infants have an immature closure mechanism, decreased sensitivity to normal constrictors, such as oxygen tension, and increased sensitivity to prostaglandin E_2, all of which promote patency. Other factors that have been associated with a PDA include severe lung disease, exogenous surfactant therapy, phototherapy, high fluid administration, early use of furosemide, and lack of antenatal glucocorticoid exposure.

The pathophysiologic effects of a PDA are determined by the direction of shunting. When pulmonary vascular resistance is high, such as with early RDS or meconium aspiration syndrome, shunting is in a right-to-left direction, resulting in mixing of deoxygenated and oxygenated blood and resultant hypoxemia. When pulmonary vascular resistance is less than systemic vascular resistance, shunting is left-to-right. Overperfusion of the lungs can alter pulmonary mechanics, causing a need for higher levels of supplemental oxygen and ventilatory support and an increase in the cardiac work load. A diastolic steal may also occur, reducing bloodflow to organs and increasing the risk of ischemic complications. Persistent PDA is also associated with increased risks for apnea, BPD, congestive heart failure, and impaired weight gain. Diagnosis and treatment of PDA is discussed in detail in Chapter 45.

Neurologic Complications

INTRAVENTRICULAR HEMORRHAGE AND PERIVENTRICULAR LEUKOMALACIA (See Ch. 40)

Premature babies requiring mechanical ventilation are at increased risk of brain injuries. The spectrum of brain injuries observed in these infants includes periventricular-intraventricular hemorrhage (PV-IVH) and periventricular leukomalacia (PVL). The main reason for the increased susceptibility to hemorrhagic or ischemic brain injuries is the unique anatomic and physiologic immaturity of brain. Absent or reduced auto-regulation of cerebral bloodflow creates pressure-passive cerebral circulation and thus renders the brain prone to damage during periods of systemic hypotension and hypertension. Cerebral circulation (and auto-regulation) is also affected by changes in Pa_{CO_2} and to a lesser extent pH. A rise in Pa_{CO_2} (hypercapnia) during the first three to four days of life is a recognized risk factor for PV-IVH. Conversely, hypocapnia (P_{CO_2} less than 35 mm Hg) is potentially dangerous, as it may cause cerebral ischemia and PVL, especially if Pa_{CO_2} decreases rapidly as can sometimes occur with the institution of HFV. Another recognized risk factor for PV-IVH is the fluctuation in cerebral bloodflow observed in babies who fight the ventilator (asynchronous breathing). The use of high PIP or PEEP can result in lung overdistention leading to increased central venous pressure, which is transmitted to cerebral veins. Increased intrathoracic pressure can also decrease venous return to the heart and thus reduce cardiac output. Additional threats to central nervous system function may come from a PDA, with right-to-left shunting, from focal or systemic infections, which initiate the inflammatory responses associated with white matter damage, and from pneumothorax or PIE, which may also aggravate respiratory failure and hemodynamic function. Concerns also exist that cerebral perfusion may be jeopardized during routine procedures, such as endotracheal tube suctioning or reintubation.

RETINOPATHY OF PREMATURITY

See also Chapter 53.

Retinopathy of prematurity (ROP) is a condition confined to the developing retinal vessels in very premature infants. The major risk factors for ROP are the degree of prematurity and high arterial oxygen content. There is higher incidence of ROP in babies with low birthweight who require mechanical ventilation and supplemental oxygen. Hyperoxia, hypoxemia, and fluctuations of arterial oxygen content, even within the normal range, have all been implicated as etiologic factors. Many other risk factors have also been suggested, including vitamin E deficiency, exchange transfusions, necrotizing enterocolitis, treatment for PDA, and other complications of prematurity. Despite meticulous neonatal care, ROP is not entirely preventable. Maintaining arterial oxygen tension between 60 to 80 mm Hg and pulse oximetry between 88% and 92% has been shown to reduce the incidence of ROP in babies who receive oxygen treatment. Nonetheless, the ideal level of oxygen saturation in ventilated preterm babies remains unknown. Ongoing large clinical trials are exploring this.[73b]

PART 5

Respiratory Disorders in Preterm and Term Infants

Jalal M. Abu-Shaweesh[*]

> And whomsoever God wills to let go astray, He causes his chest to be tight and constricted, as if he were climbing unto the skies.
>
> *Holy Quran, Al-An'am chapter, 6:125.*

Multiple pathophysiologic mechanisms can present with pulmonary manifestations in term and preterm infants. The clinical picture is most commonly dominated by respiratory distress, which presents as tachypnea, grunting, flaring, retractions, cyanosis, and hypoxemia. However, apnea and hypoventilation are also common. In preterm infants, these manifestations are commonly associated with respiratory distress syndrome (RDS) as discussed in Part 3. Nonpulmonary etiologies of respiratory distress include, thermal instability, circulatory problems, cardiac disease, neuromuscular disorders, sepsis, anemia or polycythemia, and methemoglobinemia (Box 44-11). This section presents an overview of the many other respiratory disorders that can affect preterm and term infants.

FETAL AND NEONATAL BREATHING

Although many aspects of the regulation of breathing in humans and mammals have been explored in the past century, more questions have yet to be answered. Breathing results in the exchange of PaO_2 and $PaCO_2$ between the lungs and the environment, maintaining homeostasis and control of blood pH. At the same time, energy-consuming breathing movements are present in utero, where such gas exchange is not possible. Maturation of breathing is a continuous process that bridges fetal and neonatal life. Many features of immature fetal breathing responses are present to a lesser degree in the neonate.

FETAL BREATHING

Fetal breathing activity has been described in many species and is identified very early in gestation. Breathing activity in the human fetus can be detected using ultrasound by 11 weeks' gestation. The placenta is the site of gas exchange in utero; however, fetal breathing movement (FBM) is important in enhancement of lung growth and development, and decreased diaphragmatic activity has been associated with pulmonary hypoplasia. In addition, FBM has been shown to significantly increase fetal cardiac output and bloodflow to a number of vital organs including the heart, brain, and placenta. FBM changes from early continuous movement that seems to originate from the spinal cord to a phasic pattern that occurs only during rapid eye movement (REM) in the third trimester with total cessation of breathing during non-REM sleep, possibly secondary to descending inhibitory pontine input to the medullary rhythm-generating center. The mechanisms underlying loss of phasic FBM and establishment of continuous breathing after birth are not clear.

BOX 44–11 Classification of Extrapulmonary Causes of Respiratory Distress

NEUROMUSCULAR DISORDERS (CHAPTER 40)

Central nervous system: asphyxia, hemorrhage, malformations, drugs, infection
Spinal cord: cord injury, spinal muscular atrophy
Nerves: phrenic nerve injury, cranial nerve palsy
Neuromuscular plate: myasthenia gravis
Muscular: dystrophies

OBSTRUCTIVE-RESTRICTIVE DISORDERS

Airway obstruction (Part 6)

- Intrinsic: choanal atresia, floppy epiglottis, laryngeal web, cord paralysis, laryngospasm, malacia, tracheal stenosis
- Extrinsic: tubes, secretions, Pierre Robin syndrome, macroglossia, goiter, vascular ring, cystic hygroma, mediastinal and cervical masses

Rib cage abnormalities

- Thoracic dystrophies
- Rickets and bone disease
- Fractures
- Pectus excavatum

DIAPHRAGMATIC DISORDERS

Congenital eventration
Abdominal distention

HEMATOLOGIC DISORDERS (CHAPTER 46)

Anemia
Polycythemia
Methemoglobulinemia

METABOLIC DISORDERS (CHAPTER 49)

Hypoglycemia
Hypocalcemia
Metabolic acidosis

CARDIOVASCULAR DISORDERS (CHAPTER 45)

Increased pulmonary flow

- Patent ductus arteriosus
- Ventricular septal defect
- Transposition of the great arteries
- Truncus arteriosus

Decreased pulmonary flow

- Persistent pulmonary hypertension
- Pulmonary atresia
- Tetralogy of Fallot
- Tricuspid atresia

Cardiomegaly

- Tricuspid atresia
- Ebstein anomaly
- Left heart obstruction (e.g., coarctation, mitral atresia, total anomalous pulmonary venous return)

Hypotension

MISCELLANEOUS (CHAPTERS 30, 39)

Sepsis
Pain
Hypothermia
Hyperthermia

---

[*] Richard J. Martin and Martha Miller contributed to previous editions of this chapter.

However, several factors have been implicated, including serotonin, γ-aminobutyric acid (GABA), corticotrophin-releasing factor, and prostaglandins.[2]

Fetal hypercapnia increases the incidence and depth of FBM only during REM sleep, although it does not affect breathing frequency. This response is present from 24 weeks' gestation with an increase in CO_2 sensitivity with advancing gestational age. In contrast, fetal hypocapnia causes a decrease or disappearance of FBM, which implies that baseline CO_2 level is essential for the presence of FBM. Although the fetus lives in a relatively hypoxemic condition (PaO_2 23-27 mm Hg), oxygen delivery in utero is adequate because it matches oxygen consumption and allows for fetal activity and growth. Unlike adults, the fetus responds to hypoxia by a decrease in breathing activity. The cause of this hypoxic ventilatory depression in utero appears to be central in origin. Brainstem transection or lesions in the lateral upper pons allow acute hypoxemia to stimulate FBM even in the absence of the carotid bodies. This is consistent with the concept that hypoxic depression is the result of descending pontine or suprapontine inhibition. Unlike the fetal breathing response to hypercapnia, the hypoxic response is "logical" in the sense that an increase in breathing in response to hypoxia would be counterproductive.

POSTNATAL DEVELOPMENT OF BREATHING RESPONSES

Although better developed than the fetal pattern, breathing in the neonate is still immature. This immaturity is manifested in almost all aspects of respiratory control from peripheral afferent input, to central respiratory output and respiratory muscle responses. Moreover, preterm infants exhibit more pronounced immaturity of respiratory control than term infants, the net result of which is a high incidence of apnea and bradycardia. There seems to be an overriding inhibitory influence of central origin in the control of breathing in the neonate. This is manifested by a decrease in the breathing response to CO_2, a paradoxical response to hypoxia, an exaggerated reflex apnea, and irregularities of breathing pattern manifested by periodic breathing, apnea, and tachypnea. The origin of this inhibitory effect on neonatal breathing could be secondary to increased inhibitory pathways, decreased excitatory pathways, or a combination of the two.

Neonatal Breathing Pattern

Neonatal respiratory activity is characterized by irregularity and spontaneous changes in the breathing pattern between eupnea, apnea, periodic breathing, and tachypnea. Respiratory frequency, often inversely proportional to body weight, may be quite variable in the preterm infant. Periods of slow respiratory frequency in the human neonate are secondary to prolongation of expiratory time (T_E) while inspiratory time (T_I) remains relatively unchanged during development. Extreme prolongation of T_E results in respiratory pauses and apnea, which occur frequently in preterm and, to a lesser extent, in term neonates. The incidence of central apnea decreases with advancing gestational age, occurring in almost all infants weighing less than 1000 g at birth, until 43 to 44 weeks' corrected gestational age when the incidence is comparable to that of a term neonate. Paradoxical inward movement of the rib cage during inspiration is common especially in preterm infants. The mechanisms behind this paradoxical movement are related to a combination of a highly compliant rib cage and diminished intercostal muscular tone, opposed by diaphragmatic contraction. The muscular effort required to produce a tidal volume during these paradoxical movements is substantially greater than during "normal" breathing, which further hinders an already immature breathing pattern in the neonate.

Hypercapnia and Acidosis

Small increase in arterial PCO_2 or central acidosis increases ventilation dramatically. The ventilatory response to CO_2 is the net result of activation of both peripheral and central chemoreceptors. The contribution of the peripheral chemoreceptors, mainly through the carotid body, is 10% to 40% of the total hypercapnic response. Central chemoreceptors originally thought to be confined to the ventrolateral medulla have been found to be widely spread in the brainstem, including retrotrapezoid nucleus, the region of the nucleus tractus solitarius, the region of the locus coeruleus, the rostral aspect of the ventral respiratory group, and the medullary raphe.[53] Other sites of chemoreception include the fastigial nucleus of the cerebellum and the pre-Botzinger complex. The ventilatory response to CO_2 is impaired in preterm infants when compared with term newborns and adults; however, it increases with advancing postnatal and gestational age. Unlike adults, preterm infants and newborn animals were not able to increase breathing frequency in response to CO_2 while tidal volume increased appropriately.[1] Possible mechanisms for this impaired response to CO_2 include changes in the mechanical properties of the lung, maturation in the peripheral or central chemoreceptors, or changes in the central integration of chemoreceptor or other neuronal signals. Multiple studies have indicated a central origin for the attenuated CO_2 response in preterm babies, in particular those with apnea. However, a cause-and-effect relationship between apnea of prematurity and the attenuated response to CO_2 has not been clearly established, and both might simply represent facets of a decreased respiratory drive.

Hypoxia

Unlike adults who express a sustained response to hypoxia, the neonatal hypoxic ventilatory response is biphasic with an initial increase in ventilation that lasts 1 to 2 minutes, followed by a decline that reaches below baseline ventilation in preterm infants (Fig. 44-47). This late decline has been traditionally termed *hypoxic ventilatory depression*. While the increase in tidal volume is sustained, breathing frequency decreases during hypoxic exposure, thus contributing most to the biphasic response. The increase in ventilation occurs through activation of peripheral chemoreceptors located primarily in the carotid body and is eliminated by carotid body denervation. During development, the initial rise increases while the late depression decreases with advancing postnatal age; however, hypoxic ventilatory depression persisted in convalescing preterm neonates at 4 to 6 weeks of age.[50] Several mechanisms have been postulated to explain

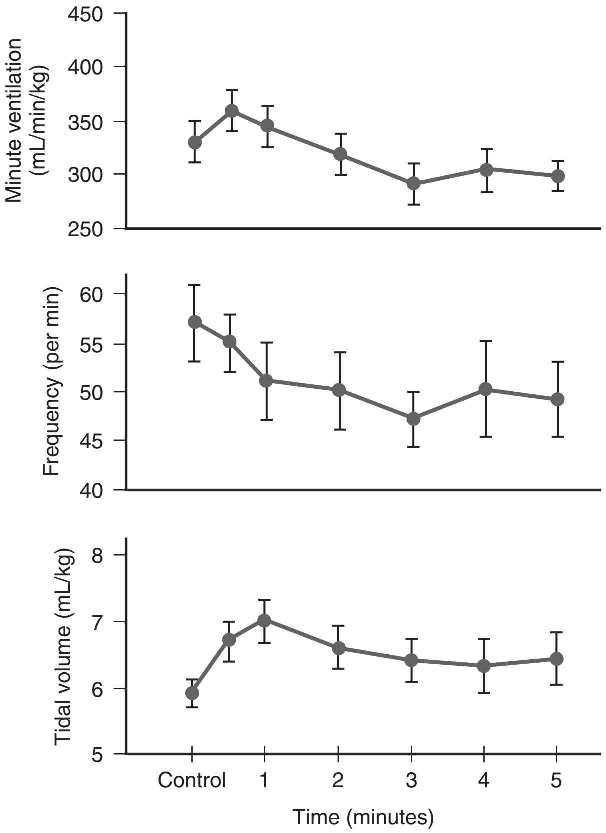

Figure 44–47. The ventilatory response to 15% hypoxia in 4- to 6-week-old preterm infants. *(From Martin RJ et al: Persistence of the biphasic ventilatory response to hypoxia in preterm infants,* J Pediatr *132:960, 1998, with permission.)*

the pathogenesis of the late depression, including a time-dependent decrease in carotid body stimulation, hypocapnea secondary to the initial hyperventilation, and a decrease in metabolism. Increasing evidence, however, suggests a central origin for hypoxic ventilatory depression, probably through interaction of multiple neurotransmitters, including adenosine, GABA, and endorphins, or through descending inhibitory pontine tracts. Consistent with these findings is the observation that a progressive decrease in inspired oxygen concentration causes a significant flattening of carbon dioxide responsiveness in preterm infants (Fig. 44-48).

Laryngeal and Pulmonary Afferent Reflexes

Stimulation of the laryngeal mucosa, either chemically (water, ammonium chloride, or acidic solutions) or mechanically, causes inhibition of breathing and apnea in neonates and newborn animals. This reflex-induced apnea, known as the *laryngeal chemoreflex* (LCR), is usually associated with glottic closure, swallowing, bradycardia, and hypotension, and has been shown to undergo maturational changes with age. Preterm infants express an exaggerated LCR as evidenced by prolonged apnea response to instilling saline in the oropharynx. The mechanisms underlying such maturational change in reflex-induced apnea are not known, but seem to be related to a decrease in central neural output or a dominance of inhibitory pathways. The inhibitory neurotransmitters adenosine and GABA have both been implicated where blockade of $GABA_A$ receptors prevented and activation of adenosine A_{2A} exaggerated the LCR.[3]

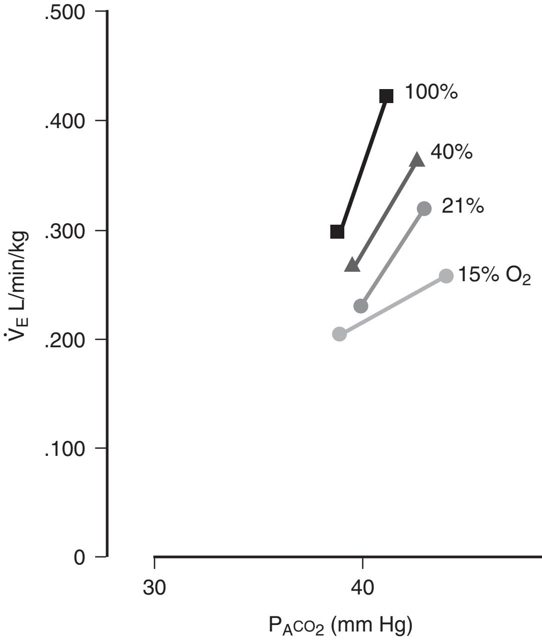

Figure 44–48. Steady-state carbon dioxide response curves at different inspired oxygen concentrations. The more hypoxic the infant, the flatter the response to carbon dioxide. *(From Rigatto H et al: Effects of O_2 on the ventilatory response to CO_2 in preterm infants,* J Appl Physiol *30:896, 1975, with permission.)*

Lung afferents play an important role in regulating respiratory timing and may play a role in apnea of prematurity. Stimulation of pulmonary stretch receptors through increasing lung volume causes shortening of inspiratory time, prolongation of expiratory time, or both. This reflex is known as the *Hering-Breuer reflex.* The decrease in respiratory frequency and prolongation of expiratory time following institution of nasal continuous positive airway pressure (CPAP) is mediated through activation of this reflex. This probably serves to prevent lung overdistention on CPAP. The Hering-Breuer deflation reflex is activated on deflation of the lung and results in inspiratory augmentation. However, unlike term infants, preterm infants are less likely to initiate breathing and tend to have respiratory pauses on deflation of the lung, thus making them less likely to recover from an apnea.

Neurotransmitters and Neuromodulators

There are limited data regarding the balance of excitatory and inhibitory neurotransmitters during development of respiratory control. Because invasive studies cannot be performed in newborn infants, most studies on the relationship of neurotransmitters to respiratory control are based on the effect of these substances or their inhibitors on the breathing responses to hypoxia, hypercapnia, and reflex apnea in animal models. The most widely studied neurotransmitters in relation to disturbances in control of breathing include adenosine, GABA, prostaglandins, endorphins, and serotonin.

GABA is the major inhibitory neurotransmitter in the central nervous system (CNS). GABA has been implicated in the attenuated ventilatory responses to hypoxia, hypercapnia, and LCR. Blocking $GABA_A$ receptors prevented hypoxic ventilatory depression and the decrease in breathing frequency in response to CO_2, and attenuated the LCR. Both structural and functional differences in $GABA_A$ receptors have been observed during development. $GABA_A$ receptors are hetero-oligomers assembled from five subunits. During embryonic and early postnatal development, the brainstem has a much higher $GABA_A$ receptor density than does the adult brainstem and the "mix" of $GABA_A$ receptor subunits differs from that in adults. Therefore, GABA has the potential to play a key role in the vulnerability of preterm infants to disturbed breathing, including apnea of prematurity. Of interest is the observation that GABA may switch from an excitatory to inhibitory neurotransmitter during the transition from fetal to neonatal life.

Adenosine is a product of ATP that is ubiquitous to most brain tissue as well as the cerebrospinal fluid (CSF). Adenosine is known to depress neural function and respiration, and its level has been shown to increase during hypoxia in brain tissue, CSF, and plasma. Furthermore, adenosine antagonists reversed hypoxic depression in anesthetized newborn piglets. The role of adenosine in apnea of prematurity is suggested by the ability of the methylxanthines, theophylline, and caffeine, which are nonspecific adenosine receptor inhibitors, to decrease the incidence of apnea of prematurity. However, the exact mechanism and location of action of adenosine, as well as the interaction of adenosine with other neurotransmitters, remain to be identified. Adenosine receptors may be inhibitory (A_3) or excitatory (A_{2B}). Recent reports have documented an interaction between adenosine and GABA in the regulation of breathing. Blockade of $GABA_A$ receptors abolished the inhibition of phrenic activity and the exaggerated LCR induced by adenosine A_{2A} agonist. Furthermore, A_{2A} receptors were found to colocalize on GABAergic neurons in the medulla oblongata of both piglets and rats. These data suggest that the mechanism of action of methylxanthines in the prevention of apnea of prematurity is through central blockade of either inhibitory A_1 receptors or excitatory A_2 adenosine receptors on GABAergic neurons.[3] In either case, respiratory inhibition is diminished.

Exogenous endorphin and enkephalin analogues have been shown to produce a consistent decrease in respiration in fetal and neonatal animals. Endorphin levels are elevated in the human neonate at birth and endogenous opioids were found to modulate the hypoxic ventilatory response in newborn infants and animals. Furthermore, the opioid antagonist naloxone produced an improvement in apnea and periodic breathing in infants in whom β-endorphin–like immunoreactivity in the CSF was elevated. Although these data support a role for opioids in respiratory control in neonates, the effect of anesthesia in such studies and the interaction of opioids with other inhibitory neurotransmitters need to be clarified. Infusion of prostaglandin E_1 (PGE_1) produces respiratory depression in 12% of infants during treatment for congenital heart disease. PGE_1 has been shown to decrease and indomethacin has been shown to enhance phrenic activity in newborn piglets.

Although the involvement of serotonin in respiratory control is well established, the nature of this involvement is complex. Both activation and inhibition of breathing have been described with different doses, routes of administration, and peripheral versus central effects. The different responses may be due, in part, to the effect on different subtypes of serotonin receptors preferentially expressed on respiratory neurons. Serotonin has been implicated as a regulatory factor in the production of apneusis. Blocking $5\text{-}HT_{1A}$ receptors has been shown to reverse apneustic breathing, which might result during hypoxia or ischemia. There is increasing evidence to suggest an important role for serotonergic neurons in the raphe nuclei in maturation of central chemoreception. This has been highlighted by findings in cohorts of sudden infant death syndrome (SIDS) victims (Japanese, African-American, and whites) in whom there was a significant positive association with the presence of a homozygous gene that encodes for the long allele of the 5-HT transporter promoter (5-HTT), as well as the long allele itself. In both studies, SIDS victims were more likely than control subjects to express the long allele of 5-HTT, as well as to miss the short allele of 5-HTT.[69] Therefore it is possible that a delay in maturation of serotonergic neurons or overexpression of the long allele for 5-HTT in the arcuate nucleus as well as in other respiratory groups might contribute to lack of respiratory responses to a stressful condition. This may be an underlying mechanism in the pathogenesis of SIDS.

Role of Astrocytes

It is becoming obvious that astrocytes play an important role in neural transmission. Astrocytes are able to release chemical transmitters including adenosine, D-serine, and glutamate, which play a role in synchronizing neuronal activity and modulating synaptic transmission. The role of astrocytes in modulation of respiration is suggested by the findings that application of methionine sulfoximine (MS), an inhibitor of glutamate release from astrocytes, in vitro to medullary slices diminished respiratory-related rhythm in the rostral medulla oblongata and decreased respiratory frequency in vivo in rats.[71]

APNEA OF PREMATURITY

Definition and Epidemiology

Apnea of prematurity has been defined most widely as cessation of breathing in excess of 15 seconds and typically accompanied by desaturations and bradycardia. Shorter episodes of apnea may also be accompanied by significant bradycardia or hypoxia. Whereas brief respiratory pauses of less than 10 seconds in duration can occur in conjunction with startles, movement, defecation, or swallowing during feeding, these short pauses are self-limited and not typically associated with bradycardia or hypoxemia. Prolonged desaturation episodes have also been reported in the absence of apnea or bradycardia, both in healthy preterm infants and more frequently in infants with chronic lung disease. These episodes might represent obstructive apnea, hypoventilation, or intrapulmonary right-to-left shunting. Although the significance of such episodes is unclear, recurrent hypoxemia has been associated with retinopathy of prematurity, necrotizing enterocolitis, and periventricular leukomalacia.

Apnea is traditionally classified into three categories based on the presence or absence of obstruction of the upper airways. These include central, obstructive, and mixed apnea. Central apnea is characterized by total cessation of inspiratory efforts with no evidence of obstruction. In obstructive apnea, the infant tries to breathe against an obstructed upper airway resulting in chest wall motion without nasal airflow throughout the entire apnea. Mixed apnea consists of obstructed respiratory efforts usually following central pauses (Fig. 44-49) and is probably the most common type of apnea followed in decreasing frequency by central and obstructive apnea. The site of obstruction in the upper airways is mostly in the pharynx; however, it may also occur at the larynx and possibly at both sites.

The incidence of apnea of prematurity is inversely related to gestational age and occurs in the vast majority of infants with extremely low birthweight. Apnea may occur from the first day of life in infants without RDS but may be delayed until several days in infants with RDS. The precise incidence of apnea depends on the diagnostic criteria employed; even so, the frequency and duration of apnea decrease with advancing postnatal age. Apnea is not exclusively confined to preterm babies in that healthy term infants were also found to have apnea exceeding 20 seconds on home monitoring.

Pathogenesis

Apnea of prematurity is a developmental disorder that probably reflects *physiologic* rather than *pathologic* immaturity of respiratory control (Table 44-5). However, despite major advances in our understanding of the control of breathing over the last decade, the exact mechanisms responsible for apnea in premature infants have not been clearly identified. This is clearly understandable in view of the limitations of studying human infants and the lack of an animal model that exhibits spontaneous apnea. Therefore most of our knowledge is derived from both physiologic studies in preterm infants and studies in immature animals. Immaturity of breathing responses in preterm infants affects all levels of respiratory control, including central and peripheral chemosensitivity, as well as inhibitory pulmonary afferents. This immaturity is manifested by impaired ventilatory responses to hypoxia and hypercapnia, and an exaggerated inhibitory response to stimulation of airway receptors, as described previously. Although a cause-and-effect relationship has not been documented for disturbed control of breathing and the occurrence of apnea in preterm infants, strong associations are very well established. Histologically, immaturity of the preterm brain is manifested by a decreased number of synaptic connections, dendritic arborizations, and paucity of myelin. Functionally, auditory evoked responses are impaired in infants with apnea when

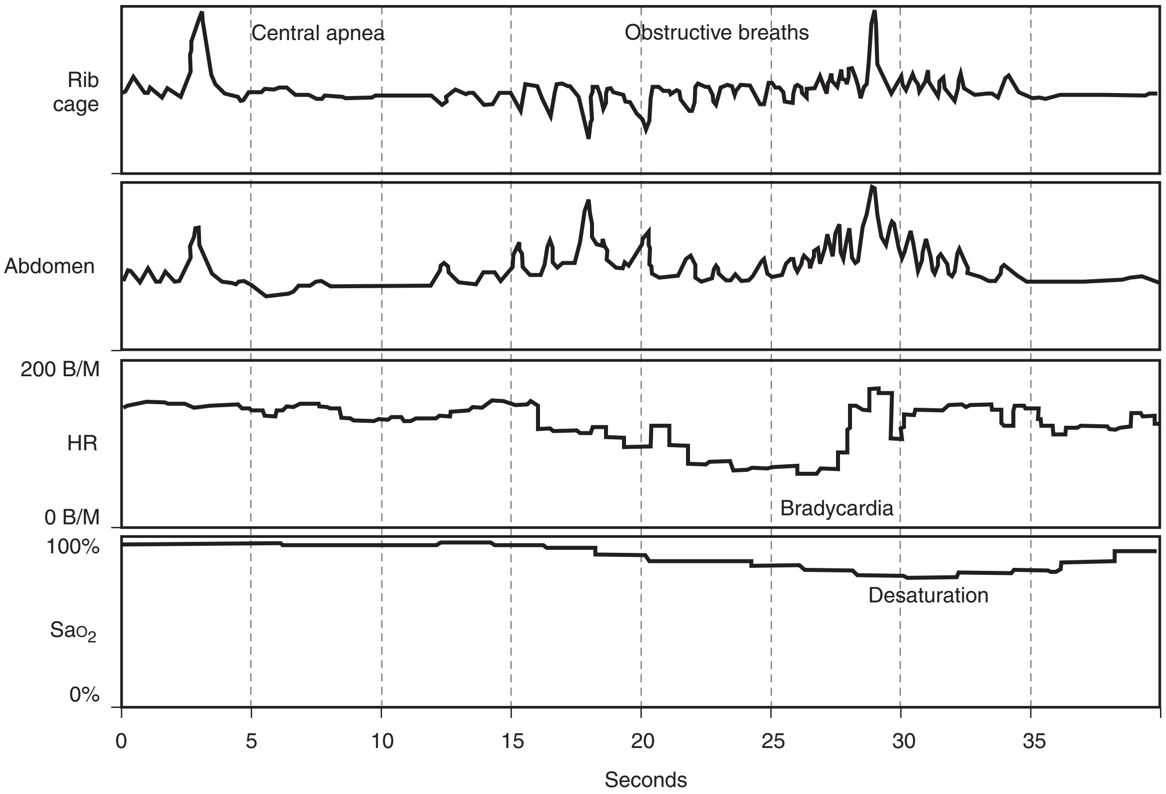

Figure 44–49. Characteristic mixed apnea of approximately 20 seconds' duration commencing with a central component and prolonged by obstructed inspiratory efforts. In the absence of simultaneous measurement of rib cage and abdominal motion as occurs during routine impedance monitoring of chest wall motion, the obstructed inspiratory efforts would not be recognized. As noted in this tracing, bradycardia and desaturation are secondary to the cessation of effective ventilation during the mixed apnea. B/M, beats per minute; HR, heart rate; SaO_2, arterial oxygen saturation.

TABLE 44–5 Factors Implicated in the Pathogenesis of Apnea of Prematurity

Central Mechanisms	Peripheral Reflex Pathways	Others
Decreased central chemosensitivity	Decreased carotid body activity	Genetic predisposition
Hypoxic ventilatory depression	Increased carotid body activity	Sepsis and cytokines
Upregulated inhibitory neurotransmitters, GABA, adenosine	Laryngeal chemoreflex	Bilirubin
	Excessive bradycardic response to hypoxia	

From Abu-Shaweesh JM, Martin RJ: Neonatal apnea: what's new? *Pediatr Pulmonol* 43:937, 2008, with permission.

compared with matched preterm control subjects, indicating delay in brainstem conduction time. Interestingly, this delay improves after treatment with aminophylline, signifying a functional rather than an anatomic immaturity.

The impairment of central chemosensitivity in preterm neonates is evident by the flat ventilatory response to CO_2 when compared with that in term neonates or adults. This impairment of hypercapnic ventilatory response is more pronounced in preterm neonates with apnea when compared with their controls without apnea. In other words, at the same level of CO_2 and for the same degree of change in alveolar CO_2, minute ventilation in babies with apnea is decreased (Fig. 44-50). Whereas exposure to hyperoxia silences the carotid body and may induce apnea, hypoxic ventilatory depression does not seem to contribute to the initiation of apnea because most infants are not hypoxic before apnea occurs. However, once apnea occurs it might prolong apnea and delay its recovery.

The peripheral chemoreceptors are located primarily in the carotid body and are responsible for stimulating breathing in response to hypoxia. Both enhanced and reduced peripheral chemoreceptor function may lead to apnea, bradycardia, or desaturations in the premature infant. In utero, the carotid chemoreceptor O_2 sensitivity is adapted to the normally low PaO_2 of the mammalian fetal environment (23 to 27 mm Hg). In response to the fourfold increase in PaO_2 with the establishment of air breathing, the peripheral chemoreceptors are silenced. This is followed by gradual increase in hypoxic chemosensitivity, although the mechanisms underlying this maturation are not completely clear.[13] A similar developmental profile has been described for both preterm and term infants. However, the contribution of immaturity of the peripheral chemoreceptors to apnea of prematurity is not clear. Maturation of peripheral arterial chemosensitivity is more or less complete by 2 weeks after birth in human infants whether the infant is term or preterm. Significant and prolonged apnea, however, can persist for many weeks to months in the most premature infants. Excessive peripheral chemoreceptor sensitivity in response to repeated hypoxia as seen in babies with bronchopulmonary dysplasia may also destabilize breathing patterns in the face of significantly fluctuating levels of oxygenation. Data in rat pups indicate that conditioning with intermittent hypoxic exposures results in facilitation of carotid body sensory discharge in response to subsequent hypoxic exposure. Furthermore, preterm infants with high frequency of apnea were found to have increased carotid body activity.[54] Hypoxia can also inhibit metabolism in the preterm infant and decrease CO_2 level, narrowing the difference between baseline CO_2 and apneic threshold CO_2 (CO_2 level below which apnea occurs). The baseline $PaCO_2$ in both preterm and term infants was found to be only 1 to 1.3 mm Hg above the apneic threshold.[39] The closeness of the apneic threshold to baseline CO_2 together with excessive activation of the carotid body might allow small oscillations of CO_2 in response to mild hyperventilation, startles, or stimulation to cause apnea. Clearly, much remains to be learned about both the short- and long-term consequences of intermittent hypoxic episodes during early development.

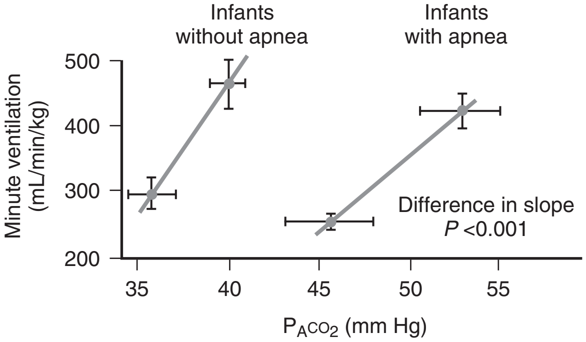

Figure 44–50. The ventilatory response to carbon dioxide has a decreased slope in infants with apnea. (*From Gerhardt T et al: Apnea of prematurity: I. Lung function and regulation of breathing,* Pediatrics *74:58, 1984. Reproduced by permission of* Pediatrics.)

While laryngeal chemoflex (LCR) is thought to be an important contributor to apnea, bradycardia, and desaturation episodes associated with feeding and gastroesophageal reflux in preterm babies, the relationship of LCR to apnea of prematurity is less clear. The association of both apnea of prematurity and LCR with swallowing movements, as well as the observation of glottic closure and swallowing in fetal lambs during spontaneous apnea, points to the possibility of a common neural network controlling both disorders. Furthermore, similar to apnea of prematurity, LCR matures with advancing gestational age and is thought to be exaggerated in immature newborns and animals secondary to decreased central neural output or a dominance of inhibitory pathways.[4]

Bradycardia is a prominent feature in preterm infants with apnea. The mechanism underlying bradycardia associated with apnea in preterm infants is not clear, although it has been postulated that bradycardia during apnea might be related to hypoxic stimulation of the carotid body chemoreceptors, especially in the absence of lung inflation (Fig. 44-51). On the

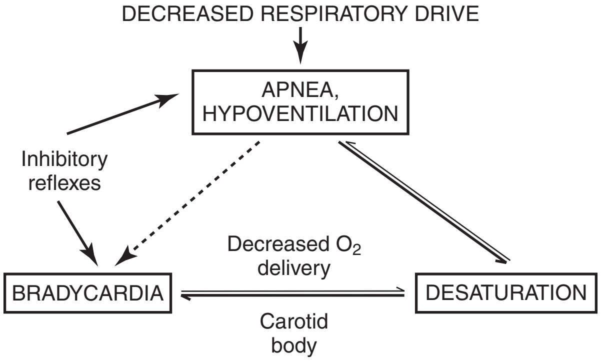

Figure 44–51. Proposed physiologic mechanisms whereby apnea induces reflex bradycardia. This can occur secondary to hypoxemia in the absence of lung inflation or by stimulation of upper airway inhibitory afferents. *(From Martin RJ, Fanaroff AA: Neonatal apnea, bradycardia or desaturation: does it matter?* J Pediatr *132:758, 1998, with permission.)*

other hand, bradycardia occurs simultaneously with apnea during stimulation of laryngeal receptors suggesting a central mechanism for the production of both. The interaction between central respiratory and cardiovascular centers in the production of bradycardia in association with apnea of prematurity clearly needs further investigation.

The effect of genetic variability on regulation of breathing and apnea is suggested by the finding of a mutation in the *PHOX2B* gene in patients with congenital central hypoventilation. Similar to preterm infants with apnea, these children are characteristically symptomatic during the initial months of life and demonstrate absent or extremely reduced ventilatory responses to CO_2 and hypoxia even though no obvious brain, muscular, cardiac, or pulmonary lesions are apparent.[28] Tamim and colleagues found a higher incidence of apnea of prematurity in infants born to first-degree consanguineous parents than in other infants.[66] These findings raise the possibility of a role for developmentally regulated genes that might contribute to the vulnerability of preterm neonates to apnea. Further studies are clearly needed to explore the role of genetics in the pathogenesis of apnea of prematurity.

Clinical Associations

Apnea can be the presenting sign or may accompany multiple disorders that affect the preterm infant. A thorough consideration of possible causes is always warranted, especially when there is an unexpected increase in the frequency of episodes of apnea and/or bradycardia (Fig. 44-52). CNS disorders, particularly intracranial hemorrhage, hypoxic ischemic encephalopathy, and malformations can precipitate apnea in the preterm infant. Upper spinal cord trauma or malformations should be considered in an otherwise healthy infant presenting with apnea at birth.

Consideration of neonatal sepsis as a potential trigger for apnea of prematurity is widely known. Only recently has insight into a novel underlying mechanism emerged. In rat pups, systemic administration of the cytokine IL-1β inhibited respiratory activity, both at rest and in response to hypoxia, and this respiratory inhibition was diminished by prior blockade of prostaglandin synthesis with indomethacin. In subsequent work from the same group of investigators, evidence was presented for IL-1β binding to IL-1 receptors on vascular endothelial cells of the blood-brain barrier during a systemic immune response. Activation of the IL-1 receptor, in turn, induces synthesis of prostaglandin E_2, which is released into respiratory-related regions of the brainstem, resulting in respiratory depression.[31] New-onset apnea or increase in baseline incidence of apnea should prompt appropriate workup for sepsis and possibly antibiotic therapy. In the older infant, the presentation of respiratory syncytial virus (RSV) and other viral infections is sometimes heralded by apnea.

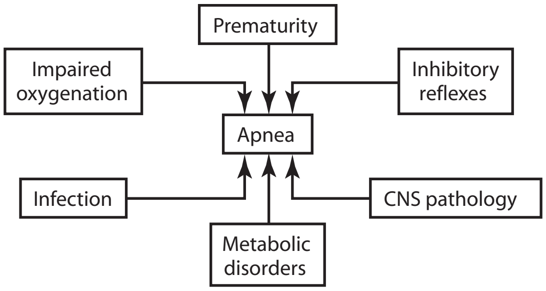

Figure 44–52. Specific contributory causes of apnea. CNS, central nervous system. *(From Martin RJ et al: Pathogenesis of apnea in preterm infants,* J Pediatr *109:733, 1986, with permission.)*

Anemia, another frequent problem in preterm infants, whether iatrogenic or secondary to bleeding, is a potential precipitating factor. Blood transfusions can improve irregular breathing patterns in preterm infants, although the limited benefit and potential risk of blood transfusion have limited its use as treatment for apnea. Other disease states that may precipitate apnea include metabolic disorders such as hypoglycemia, hypocalcemia, and electrolyte imbalance. Temperature instability and metabolic acidosis may be associated with apnea, although there is always the risk that sepsis is the underlying cause. Medications including opiates, benzodiazepines, magnesium sulfate, and PGE_1 can all precipitate apnea.

Gastroesophageal Reflux and Neonatal Apnea

Gastroesophageal reflux (GER) is often incriminated in causing neonatal apnea. Despite the frequent coexistence of apnea and GER in preterm infants, investigations of the timing of reflux in relation to apneic events indicate that they are rarely temporally related. Furthermore, when apnea and reflux coincide, there is no evidence that GER prolongs the concurrent apnea. Although physiologic experiments in animal models reveal that reflux of gastric contents to the larynx induces reflex apnea, there is no clear evidence that treatment of reflux will affect the frequency of apnea in most preterm infants. Therefore, pharmacologic management of reflux with agents that decrease gastric acidity or enhance gastrointestinal motility generally should be reserved for preterm infants who exhibit signs of emesis or regurgitation of feedings, regardless of whether apnea is present. Most recent studies have employed multichannel intraluminal impedance in addition to monitoring esophageal pH. This allows respiratory pauses to be correlated with both acidic and nonacidic bolus events in the esophagus and has allowed postprandial (nonacid) events to be carefully characterized. Currently available data with this new technique also do not readily support a clear relationship between gastroesophageal reflux and apnea in preterm infants, again raising doubts about the efficiency of widespread antireflux medication use in this population.[64]

Continuous Positive Airway Pressure Therapy

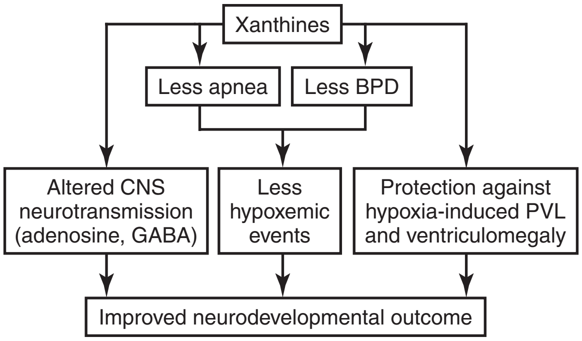
CPAP therapy at 4 to 6 cm H_2O has been used safely and effectively for more than 35 years. Because longer episodes of apnea frequently involve an obstructive component, CPAP appears to be effective by splinting the upper airway with positive pressure and decreasing the risk of pharyngeal or laryngeal obstruction. CPAP also benefits apnea by increasing functional residual capacity, thereby improving oxygenation status. At a higher functional residual capacity, time from cessation of breathing to desaturation and resultant bradycardia is prolonged. High-flow nasal cannula therapy has been suggested as an equivalent treatment modality that may allow CPAP delivery while enhancing mobility of the infant. This approach is widely taken, although it has not been well studied. In fact, considerable questions have been raised about the safety and efficacy of devices that provide relatively unregulated high flow as a means of CPAP delivery. While the mode of delivery for low CPAP in preterm infants will continue to be refined, CPAP use for ventilatory support and treatment of apnea is more widely used than ever in neonatal intensive care (see also Part 4).

Xanthine Therapy

Methylxanthines have been the mainstay of pharmacologic treatment of apnea of prematurity for more than 30 years. Both theophylline and caffeine are used, and both have multiple physiologic and pharmacologic mechanisms of action. Xanthine therapy increases minute ventilation, improves CO_2 sensitivity, decreases hypoxic depression of breathing, enhances diaphragmatic activity, and decreases periodic breathing. The precise pharmacologic basis for these actions, which are mediated by an increase in respiratory neural output, is still under investigation, although competitive antagonism of adenosine receptors is a well-documented effect of xanthines. While adenosine acts as an inhibitory neuroregulator in the CNS via activation of adenosine A_1 receptors, an effect on adenosine A_{2A} receptors' activation of GABAergic neurons, described earlier, might also play a role. The methylxanthines have some well-documented acute adverse effects. Toxic levels may produce tachycardia, cardiac dysrhythmias, feeding intolerance, and infrequently, seizures, although these effects are seen less commonly with caffeine at the usual therapeutic doses. Mild diuresis is caused by all methylxanthines. The observation that xanthine therapy causes an increase in metabolic rate and oxygen consumption of approximately 20% suggests that the caloric demands may be increased with this therapy at a time when nutritional intake already is compromised. A large international multicenter clinical trial has been completed in which preterm infants were randomized to caffeine versus placebo therapy. This study was designed to test short- and long-term safety of this therapy. Initial evaluation of the findings has revealed a significant reduction in the postmenstrual ages at which both supplemental oxygen and endotracheal intubation were needed. Subsequent reports of neurodevelopmental outcome are also very encouraging with evidence for a significant decrease in cerebral palsy and cognitive delay in the caffeine treated group.[62] This finding raises interesting questions regarding possible mechanisms underlying this beneficial effect of caffeine on neurodevelopmental outcome (Fig. 44-53). These include the observation in animal models that loss of the adenosine A_1 receptor gene or caffeine administration are protective against hypoxia-induced loss of brain white matter and ventriculomegaly.[10] Furthermore, caffeine was found to increase amplitude and periods of continuity of EEG in preterm infants.[65a] While caffeine clearly decreases apneic episodes in preterm infants, the effect of caffeine on hypoxemic episodes is unclear; earlier data have not shown a clear benefit, making this worthy of further study.

Other Therapeutic Approaches

Any approach to nursing care that optimizes the infants' well-being is clearly highly desirable. "Kangaroo" care, or skin-to-skin nursing, has achieved widespread acceptance for stable infants, and provides an opportunity for greater parental involvement. Although the advocates of this approach have suggested a decrease in apnea rates, recent data have not supported this impression. Meanwhile, research on the biologic basis of sleep and awake states needs to be translated into preventive strategies for apnea.[46] There is considerable interest in identifying the optimal target oxygen saturation (e.g., 85% to 89% versus 91% to 95%) for preterm infants, and this issue is not yet resolved. One might anticipate that desaturation accompanying apnea will be greater at lower baseline SaO_2, but this has not been well documented. It has



Xanthines
Less apnea
Less BPD
Altered CNS neurotransmission (adenosine, GABA)
Less hypoxemic events
Protection against hypoxia-induced PVL and ventriculomegaly
Improved neurodevelopmental outcome

Figure 44–53. Multiple proposed mechanisms for improved neurodevelopmental outcome associated with xanthine therapy for apnea of prematurity. BPD, bronchopulmonary dysplasia; CNS, central nervous system; GABA, γ-aminobutyric acid; PVL, periventricular leukomalacia. *(From Abu-Shaweesh JM, Martin RJ: Neonatal apnea: what's new?* Pediatr Pulmonol *43:937, 2008, with permission.)*

also been assumed, although unproven, that enhanced oxygen-carrying capacity, as with red blood cell transfusion, may decrease the likelihood of hypoxia-induced respiratory depression and resultant apnea. A novel approach is supplementation of inspired air with a very low concentration of supplemental CO_2 to increase respiratory drive. While of great interest from a physiologic perspective, and likely to be successful in decreasing apnea, it is doubtful that this would gain widespread clinical acceptance.

Resolution and Consequences of Apnea of Prematurity

Apnea of prematurity generally resolves by about 36 to 40 weeks' postconceptional age. However, in more immature infants, apnea frequently persists beyond this time. Data indicate that cardiorespiratory events in such infants return to the baseline "normal" level at about 43 to 44 weeks' postconceptional age. In other words, beyond 43 to 44 weeks' postconceptional age, the incidence of cardiorespiratory events in preterm infants does not significantly exceed that in term babies. For a subset of infants, the persistence of cardiorespiratory events may delay hospital discharge. In these infants, apnea longer than 20 seconds is rare; rather, these infants exhibit frequent bradycardia to less than 70 or 80 beats per minute with short respiratory pauses.[22] The reason some infants exhibit marked bradycardia with short pauses is unclear, but data suggest a vagal phenomenon and benign outcome. For a few of these infants, home cardiorespiratory monitoring, until 43 to 44 weeks' postconceptional age is offered in the United States as an alternative to a prolonged hospital stay.

The problem of correlating apnea with outcome is compounded by the fact that nursing reports of apnea severity may be unreliable, and impedance monitoring techniques fail to identify mixed and obstructive events. Despite these reservations, data suggest a link between the number of days that apnea and assisted ventilation were recorded during hospitalization and impaired neurodevelopmental outcome. A relationship between delay in resolution of apnea and bradycardia beyond 36 weeks' corrected age and a higher incidence of unfavorable neurodevelopmental outcome has also been recently shown.[57] Finally, a high number of cardiorespiratory events recorded after discharge via home cardiorespiratory monitoring appears to correlate with less favorable neurodevelopmental outcome. Future studies might better focus on the incidence and severity of desaturation events, in that techniques for long-term collection of pulse oximeter data are now more advanced. Furthermore, it is likely that recurrent hypoxia is the detrimental feature of the breathing abnormalities exhibited by preterm infants. For example, neonatal mice exhibiting hyperoxia-induced lung injury and exposed to intermittent hypoxia exhibit neurofunctional handicap when compared with normoxic mice with lung injury not subjected to intermittent hypoxia. Former preterm infants appear to be at greater risk of later sleep-disordered breathing, and recent data link xanthine use for apnea of prematurity with later sleep-disordered breathing. Recurrent episodes of desaturation during early life and resultant effects on neuronal plasticity related to peripheral or central respiratory control mechanisms may serve as the underlying mechanisms for such a putative relationship.

Apnea and Sudden Infant Death Syndrome

The apparent lack of a relationship between persistent apnea of prematurity and SIDS has become clearer in recent years. In fact, no clinical evidence reliably links a physiologic ventilatory control abnormality to SIDS. SIDS continues to be the leading cause of postneonatal mortality with a peak incidence at 2 to 3 months of age and during winter months. SIDS continues to be a diagnosis of exclusion and in 2004 an expert panel defined SIDS as "the sudden and unexpected death of an infant under 1 year of age, with onset of the lethal episode apparently occurring during sleep, that remains unexplained after a thorough investigation including performance of a complete autopsy, and review of the circumstances of death and the clinical history." Certain risk factors have been consistently identified such as nonsupine sleep position, sleeping on a soft surface, maternal smoking during pregnancy, overheating, late or no prenatal care, young maternal age, preterm birth and/or low birthweight, male gender, and African American, American Indian, or Alaska native race. The use of pacifier has been associated with a protective effect on the occurrence of SIDS (odds ratio [OR], 0.39; 95% confidence interval [CI], 0.31-0.50).[30] Malloy and associates have shown that the mean postconceptional age at which SIDS occurs in preterm infants is younger than that of term infants. Clinically significant apnea has resolved by that postnatal age (Fig. 44-54).[49] The incidence of SIDS has decreased by more than half with the introduction of the international campaign to avoid all sleep positions except supine. However, the relative contribution of other risk factors including maternal smoking and socioeconomic factors to the incidence of SIDS increased during the same period (Fig. 44-55),[25] emphasizing the need for targeting these factors in order to further decrease the risk of SIDS.

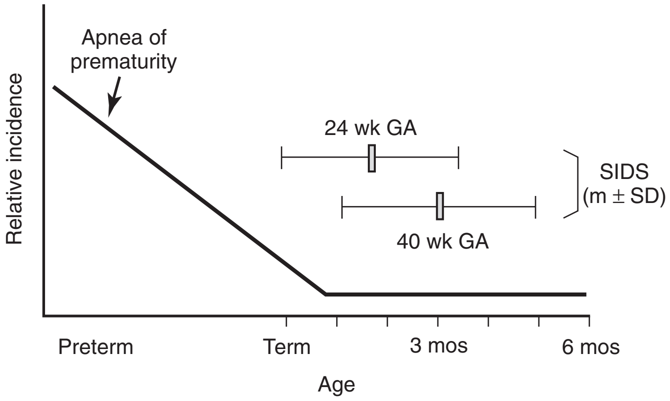


Figure 44–54. Schematic representation of the timing of sudden infant death syndrome (SIDS) in term (40 weeks' gestation) and very preterm (24 weeks' gestation) infants, in relation to the decline in incidence of apnea of prematurity. It would appear that apnea has largely resolved by 44 weeks' postconceptional age, which is prior to the peak incidence of SIDS at all gestational ages (GA).

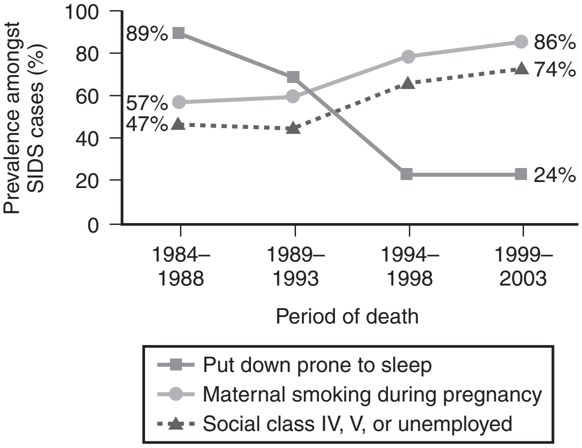

Figure 44–55. The prevalence of risk factors among victims of sudden infant death syndrome with the Back to Sleep campaign. Social class IV, semi-skilled occupation Social class V, unskilled occupation *(Adapted from Fleming P, Blair PS: Sudden infant death syndrome and parental smoking,* Early Hum Dev *83:721, 2007, with permission.)*

The triple risk hypothesis has been widely adapted as an explanation for the pathophysiology of SIDS. It states that SIDS occurs in vulnerable at-risk infants during a developmental duration of risk and is precipitated by an acute insult. Vulnerability of SIDS victims may come from the environmental risk factors mentioned earlier, together with alcohol consumption during pregnancy, especially in Native Americans, as well as a genetic predisposition that includes the abnormalities of the serotonin system described previously. The peak incidence of SIDS (1 to 6 months of age) constitutes the developmental duration of risk, and the actual final insult might include apnea, asphyxia, or the LCR described previously.

DEVELOPMENTAL LUNG DISEASES

Pulmonary Agenesis/Hypoplasia

Abnormal lung development varies from complete agenesis of one lung or lobe of a lung to mild lung hypoplasia. It can also be classified as primary or secondary. Complete agenesis of the lung is usually unilateral, although dysgenesis of the other lung might also be present. While lung agenesis can be an isolated finding, it is commonly associated with other congenital malformations including renal, vertebral, cardiac, and gastrointestinal, as well as malformations of the first and second arch derivatives and radial ray defects. As a result, it was suggested that pulmonary agenesis may occur as an alternate to tracheoesophageal fistula in the VACTERL (V, *v*ertebral anomalies; A, *a*nal atresia; C, *c*ardiac defect; TE, *t*racheo*e*sophageal fistula; R, *r*enal abnormalities; L, *l*imb abnormalities) sequence or as part of the Goldenhar anomaly. In a review of 71 cases of lung agenesis, the defect was unilateral in 90% of the cases (49% on the right and 41% on the left) and bilateral in 10% of the cases.[20] There is usually compensatory hypertrophy of the contralateral lung with herniation to the affected hemithorax. Diagnosis is confirmed on antenatal ultrasound by the presence of mediastinal shift in the absence of diaphragmatic hernia. Antenatal echocardiogram reveals total absence of the pulmonary artery or one of its branches on the affected side. Magnetic resonance imaging (MRI) examination can confirm the diagnosis, evaluate the size of the remaining lung, and evaluate the presence of other congenital malformations.

Unilateral or bilateral pulmonary hypoplasia is classified as *primary,* caused by intrinsic failure of normal lung development, or *secondary,* caused by multiple pathologic processes that interfere with normal lung development. Pulmonary hypoplasia is present in up to 33% of patients with oligohydramnios and can be associated with a high mortality rate (55% to 100%) depending on the severity of hypoplasia. (See also Chapter 22.) The pathophysiology of secondary pulmonary hypoplasia includes (1) oligohydramnios secondary to renal malformations, prolonged early amniotic fluid leak, placental abnormalities, or intrauterine growth restriction, (2) space-occupying lesions compressing the lungs and preventing normal growth as seen with congenital diaphragmatic hernia, cystic lung disease, or cardiac malformations with extreme cardiomegaly (e.g., tricuspid atresia or Ebstein anomaly), and (3) absence or abnormal diaphragmatic activity (that is essential for lung development) resulting from central or peripheral nervous disorders or musculoskeletal disease. Antenatal diagnoses can be achieved using different ultrasonography measurements including thoracic circumference (TC) corrected for gestational age or femur length, TC/abdominal circumference ratio, and *thoracic/heart area*. Recently, measurement of lung volume using three-dimensional ultrasound corrected for gestational age carried the best diagnostic accuracy versus three-dimensional ultrasound measurements. In addition to evaluation of the size of the lung, MRI can also diagnose associated anomalies that might be contributing to hypoplasia. Pathologic examination of the hypoplastic lung can show low ratio of lung to body weight, low DNA content, or decreased radial alveolar count. Peripheral bronchioles are decreased in number, as are the pulmonary arterioles, which often exhibit hypertrophy of medial smooth muscle, thus predisposing to persistent pulmonary hypertension.

After delivery, diagnosis of infants with unilateral pulmonary agenesis can be suspected by decreased breath sounds and displacement of the mediastinum to the affected side. Some breath sounds, however, may be audible over the affected side if a portion of normal lung has herniated across the midline. The radiographic appearance of a radiopaque hemithorax helps confirm the diagnosis, and accompanying vertebral defects are not uncommon (Fig. 44-56). Treatment is largely supportive, and prognosis depends on the presence or absence of other anomalies.

Secondary pulmonary hypoplasia is most commonly encountered in oligohydramnios and congenital diaphragmatic hernia (CDH). Survival of these infants depends on the degree to which lung growth is restricted and the underlying cause of hypoplasia. It is not uncommon for these patients to present with severe respiratory distress associated with bilateral pneumothorax. Patients with pulmonary hypoplasia secondary to prolonged premature rupture of membranes (PPROM) starting in the second trimester have recently been shown to have a better prognosis than initially expected. In a review of 98 deliveries with PPROM starting at 20 weeks' gestation, survival using modern neonatal therapies was 70% and medical history was not helpful

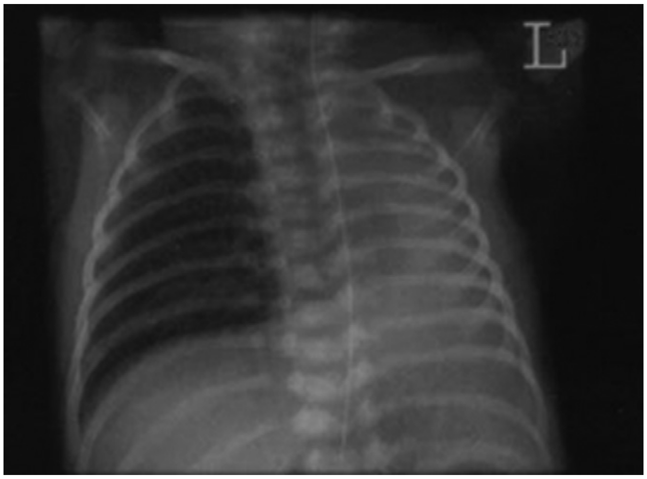

Figure 44–56. Unilateral left lung agenesis. *(From Greenough et al: Greenough A, Ahmed J, Broughton S: Unilateral pulmonary agencies, J Perinat Med 34:80, 2006. Perinat Med 34:80, 2006, with permission.)*

in predicting survival.[24] Both human and animal studies have shown that some of these infants who present with early severe respiratory failure consistent with pulmonary hypoplasia may benefit from inhaled nitric oxide (iNO). This treatment should be used with caution in premature infants, as some might have a dramatic response to iNO causing a rapid and extreme increase in Pa_{O_2}. Unlike term neonates, these babies usually do not show rebound persistent pulmonary hypertension (PPHN), and fast weaning of the inspired oxygen should be attempted.

Congenital Diaphragmatic Hernia (see Part 8)

Congenital diaphragmatic hernia occurs as a result of displacement of abdominal contents into the chest cavity through posterolateral or central diaphragmatic defects causing Bochdalek and Morgagni hernias, respectively. The incidence is between 1 in 2200 to 4000 live births, and it occurs most commonly on the left side (85%), while bilateral hernias are rare (1%) and mostly fatal. CDH is commonly associated with multiple congenital anomalies including cardiac, urogenital, chromosomal, syndromic, and musculoskeletal. The reported incidence of associated malformations varies between 20% and 60% depending on the method of diagnosis, the inclusion of autopsy cases or aborted fetuses, and whether extensive evaluation was performed. In a recent review of 3062 patients with CDH, the Congenital Diaphragmatic Hernia Study Group reported an incidence of 28% of severe malformations (major cardiac, syndromal and chromosomal disorders) in patients who did not undergo surgical repair secondary to unsalvageable hernia compared with 7% in repaired patients.[16] This emphasizes the importance of adequate evaluation of associated malformations in patients with CDH.

The underlying pathophysiology of CDH is that of pulmonary insufficiency and PPHN secondary to pulmonary hypoplasia, lower number of alveoli, and airway and vascular muscular hypertrophy associated with compression by abdominal contents. Pulmonary hypoplasia may also have a primary developmental component, in that animal models have confirmed that developmental regulation of the lung and diaphragm are controlled by some of the same genes. The severity of CDH is related mostly to the degree of hypoplasia, which depends on the size of the defect,[16] the presence of the liver in the chest, and how early in gestation the abdominal contents were displaced. In a review of reports from 13 tertiary centers, 56% of CDH cases were diagnosed antenatally. Antenatal diagnosis is associated with a poor prognosis, and the data suggest that infants with a prenatal diagnosis had a better chance of survival if they were born in a tertiary center.[48] Several antenatal parameters have been evaluated for their ability to predict survival and morbidity in isolated CDH, including lung area to head circumference ratio (LHR), lung to chest transverse diameter ratio, the presence of fetal liver in the chest, estimated fetal lung volume by MRI and three-dimensional ultrasound corrected for body weight or gestational age, and size of pulmonary artery.[34] Even though most of these studies have reported lower values of lung volume assessment in patients with CDH when compared with standard measurements, the ability of these parameters to predict survival has not been consistent. This is mostly secondary to small number of patients in each series, challenges in measurement consistency, absence of standardized measurement and lack of correlation with actual lung volume, and inconsistent measures for survival or morbidity. Nevertheless, in a recent multicenter study involving 184 patients with isolated left CDH, there were no survivors in this large cohort in patients with liver herniation and LHR less than 0.8, and only 3 of 27 infants (11%) with LHR less than 1 survived. In comparison, survival was 58% (11 of 19) in fetuses with LHR greater than 1 and without liver herniation.[37] Even though the data from MRI and three-dimensional ultrasound studies look promising, they need further validation in larger group of patients. Postnatal factors associated with increased mortality and morbidity include low 5-minute Apgar score (0-3), size of the diaphragmatic defect (OR,14 for mortality with agenesis of the diaphragm), and need for patch repair.[16]

The clinical presentation of patients with CDH can vary from asymptomatic in mild cases to severe respiratory failure at birth. Diagnosis should be suspected in previously undiagnosed patients by the presence of severe respiratory distress, cyanosis, scaphoid abdomen, and failure to improve with ventilation. Physical examination reveals absence of air entry on the affected side with displacement of heart sounds to the contralateral side. Sometimes bowel sounds can be heard over the chest cavity. Once the diagnosis is made or suspected, patients should be immediately intubated and an orogastric tube placed to evacuate the stomach. Hyperventilation and escalation of peak inspiratory pressure (PIP) should be avoided (see later). Chest radiograph shows the presence of bowel loops in the affected chest cavity with shifting of the heart to the contralateral side (Fig. 44-57). If the stomach is included in the hernia, the tip of orogastric tube will overlie the affected chest cavity. The presence of liver in the chest is suspected by deviation of the umbilical venous line. Late presentation of Bochdalek hernia occurs in 5% to 10% of cases. These patients can be asymptomatic at birth and usually present later in life with respiratory or gastrointestinal symptoms. High index of suspicion is needed in these cases to prevent unwarranted and potentially dangerous interventions like insertion of a chest

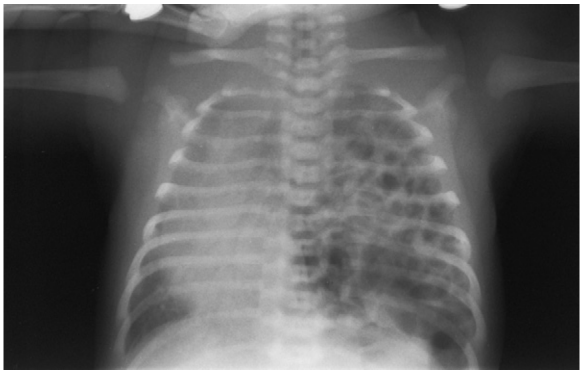

Figure 44–57. Left-sided diaphragmatic hernia in a 1-day-old term infant.

tube for suspected pleural effusion or pneumothorax. Diagnosis can be made after nasogastric tube insertion, contrast upper gastrointestinal study, or chest computed tomography (CT) scan. Prognosis for cases with late presentation is excellent once the correct diagnosis is made.

Improved survival has been reported recently using a consistent approach in the management of CDH that can be facilitated by the development of multidisciplinary standardized treatment guidelines, including input from neonatology, pediatric surgery, extracorporeal membrane oxygenation (ECMO) specialists, and respiratory therapy (Box 44-12). Predetermined criteria for the use of ECMO and an underlying "protect the lung" strategy are essential components in the care of these infants and can be as important as the specific medical interventions chosen. Whereas animal studies have suggested lung immaturity and surfactant deficiency in animal models of CDH, the use of antenatal steroids and surfactant replacement has not been shown to be beneficial. On the contrary, a bolus dose of surfactant may be associated with sudden irreversible decompensation that requires ECMO. A recent systematic review of strategies associated with improved survival among infants with CDH in 13 centers that cared for at least 20 patients and reported a survival rate of 75% or more has described multiple successful treatment strategies associated with this improved survival.[48] Although these centers used different mechanical ventilation strategies, most of these targeted the use of gentle ventilation or permissive hypercapnia. The basic elements of this treatment strategy are:

1. Setting ventilatory pressure limits that should not be exceeded to prevent lung damage secondary to volutrauma. The pressure limits varied in different centers between 20 to 25 and 30 to 35 cm H_2O for PIP and 12 to 18 cm H_2O for mean airway pressure.
2. Accepting preductal saturations of greater than or equal to 85%, regardless of postductal saturation, and higher Pa_{CO_2} levels of less than or equal to 65 with pH of at least 7.25 as long as there is evidence of adequate tissue perfusion and oxygenation evaluated by pH and lactate levels.
3. Instituting high-frequency oscillatory ventilation (HFOV) or high-frequency positive pressure ventilation once the preset limit failed to achieve adequate saturations or Pa_{CO_2} levels, although HFOV was used by some as the primary mode of ventilation.
4. Even though iNO might produce short-term benefits, the routine use of iNO is not supported by current data and might actually be associated with worse outcome.
5. Using ECMO as rescue therapy with variable indications in different centers including persistent oxygenation index (OI) above 40, persistent hypoxemia, or failure of ventilatory management to support oxygenation, ventilation, or tissue perfusion.
6. Delaying surgical repair until physiologic stabilization and improvement of PPHN.

Questions regarding the use of chest tubes, repair on or off ECMO, and benefits of various options for surgical reconstruction of large defects remain to be answered.

The overall survival using this approach in the management of 763 infants with symptomatic CDH was 79%, while that for isolated CDH was 85%. Survival was approximately 70% and 90% for patients with isolated CDH with and without need for ECMO, respectively. Mortality was generally attributed to the presence of additional anomalies, iatrogenic lung injury, severe pulmonary hypoplasia or PPHN, and bleeding complications among ECMO-treated infants. However, the survival data might underestimate hidden mortality secondary to termination, rate of diagnosis, and referral pattern for outborn patients. Infants born with CDH have multiple long-term morbidities affecting the pulmonary, gastrointestinal, and skeletal systems. Respiratory complications include pulmonary vascular abnormalities presumably causing pulmonary hypertension, a higher incidence of obstructive airway disease, and a restrictive lung function pattern. Gastroesophageal reflux disease sometimes in

BOX 44–12 Management of Congenital Diaphragmatic Hernia

RESOLVED ISSUES

There is a high incidence of associated malformations.

Delivery at a tertiary center improves survival for antenatally diagnosed cases.

Agenesis of the diaphragm and herniation of the liver are poor prognostic signs.

Multidisciplinary approach using gentle ventilation improves outcome.

Survivors need long-term follow-up and management of associated complications.

UNRESOLVED ISSUES

The utility of antenatal ultrasound and magnetic resonance imaging markers to predict survival

The role of antenatal steroids, surfactant, and inhaled nitric oxide in management

Surgical approach

Benefit of extracorporeal membrane oxygenation (ECMO) and use of chest tube

RECOMMENDATIONS

Accept preductal saturations $\geq$ 85%, $Pa_{CO_2} \leq 65$, and pH ≥ 7.25.

Identify preset ventilatory limits not to be exceeded.

Use of high-frequency oscillatory ventilation if CMV, conventional mechanical ventilation fails

Use of ECMO per preset criteria

Delay surgery until persistent pulmonary hypertension improves.

combination with failure to thrive is a well-recognized complication in patients with CDH and several patients require antireflux surgery. It is unknown whether GERD has an effect on pulmonary function in this population. Pulmonary hypoplasia and PPHN predispose children born with CDH to a high risk for hypoxemia, which may result in neurodevelopmental delay. Chest wall deformities and scoliosis are more common among CDH patients, although deformities are mild and surgery is rarely required.[55] These data emphasize the need for multidisciplinary team approach in the postoperative management and follow-up of all survivors of CDH.

Capillary Alveolar Dysplasia

Capillary alveolar dysplasia (CAD) is a rare fatal pulmonary disease that usually presents in the newborn period with severe hypoxemia and PPHN unresponsive to treatment. Although the disease is mostly sporadic, reports of multiple affected siblings in subsets of families suggest an autosomal recessive inheritance. CAD is a pathologic diagnosis that is mostly identified at autopsy while 10% can be diagnosed with antemortem lung biopsy. Histologically, CAD is characterized by paucity of capillaries proximal to the alveolar epithelium, anomalous distended pulmonary veins within the bronchovascular bundle instead of the interlobular septa, and immature alveolar development with medial thickening of small pulmonary arteries and muscularization of the arterioles. These characteristic findings are diffuse in 85% of patients and patchy in the rest. While the mechanisms underlying PPHN are not clear, they are probably related to capillary hypoplasia, impaired pulmonary bloodflow secondary to discontinuity of capillaries, and pulmonary veins and reactive pulmonary vasoconstriction mediated by hypoxia that might respond transiently to pulmonary vasodilators.[63] Multiple other congenital nonlethal malformations might be associated with CAD. These include gastrointestinal (30%), cardiac (30%), renal (23%), right-left asymmetry as well as CDH, and phocomelia.

Most patients with CAD present within the first few hours of life. These infants are usually born at term and have appropriate size and normal Apgar scores. Although these babies might be asymptomatic at delivery, respiratory distress, cyanosis, and hypoxemia progress quickly to respiratory failure in more than half of these patients within hours after delivery. About 14% of these patients do not present with symptoms until 2 to 6 weeks of life. Treatment is always unsatisfactory. Although transient response to iNO might be observed, this is usually short lasting. PPHN is not responsive to medical treatment and the disease progression is that of a fulminant course and rapid progression to death, although there are reports of survival beyond the neonatal period. High index of suspicion and diagnostic lung biopsy are required to avoid the use of more invasive and futile treatments, including ECMO.

Congenital Pulmonary Lymphangiectasia

Congenital pulmonary lymphangiectasia (CPL) is a rare disorder of term neonates although presentation in preterm infants has been described. Most cases of CPL are sporadic with predilection for male involvement (2:1). However, familial presentations suggestive of autosomal recessive inheritance have been described. CPL is classified as primary or secondary. Primary CPL can present as a diffuse or localized primary pulmonary developmental defect or as a part of more generalized lymphatic involvement. Patients with generalized lymphangiectasia tend to have less severe pulmonary involvement. Secondary cases of CPL are mostly seen with cardiac malformations associated with obstructed pulmonary venous return including total obstructed anomalous pulmonary venous return, hypoplastic left heart syndrome, and cor triatrium. CPL has also been described in multiple syndromes including Noonan, Down, and Ullrich-Turner. The characteristic pathologic finding of CPL is pulmonary lymphatic dilation in the subpleural, interlobar, perivascular, and peribronchial lymphatics.

The etiology of CPL is not clear but is thought to be secondary to failure of regression of lymphatics that occurs normally between 16 and 20 weeks' gestation. Recently, multiple genes have been found to be involved in lymphatic development, including *FOXC2,* vascular endothelial growth factor 3, and integrin $\alpha9\beta1$ genes. Mice homozygous for a null mutation in the integrin $\alpha9$ subunit gene died of respiratory failure due to bilateral chylothorax within 6 to 12 days after birth with pathologic features similar to those in CPL. Patients with CPL usually present with intractable respiratory failure, cyanosis, and hypoxia associated with bilateral chylothorax in the first few hours of life, although diagnosis can be delayed for several weeks in cases of unilobar involvement. Nonimmune hydrops is also a well-recognized presentation in patients with CPL. Examination of the pleural fluid shows characteristic findings of chylothorax with lymphocytosis, although elevated triglycerides might be absent in nonfed infants (see later). Chest radiograph reveals hyperinflation of the lung with bilateral interstitial infiltrates and bilateral pleural effusions. High-resolution computed tomography demonstrates diffuse thickening of the peribronchovascular interstitium and the septa surrounding the lobules. Definitive diagnosis is made by lung biopsy showing the characteristic features, although differentiation from lymphangiomatosis can be difficult.[11]

Treatment is mostly supportive. Intubation and mechanical ventilation, drainage of pleural and peritoneal effusions, correction of hypoxia, acidosis, and shock might be needed in the delivery room for stabilization. Persistent chylothorax might require chest tube placement. Genetic therapy involving VEGF might be promising in patients with severe involvement. Prognosis appears to depend on the severity of symptoms in the immediate newborn period. Although traditionally thought to be fatal, there are recent reports of survival in some patients who present in the immediate neonatal period with respiratory failure, chylothorax, and hydrops fetalis. Later presentation carries a better prognosis with the possibility of spontaneous resolution, although respiratory morbidity might be common.

Chylothorax

Chylothorax or the accumulation of lymph fluid in the pleural cavity is the commonest cause of clinically significant pleural effusion in neonates and can be congenital or acquired. Congenital chylothorax can be seen in association with multiple congenital malformations that result in poor development or obstruction of the lymphatic system. These include pulmonary lymphangiectasia, lymphangiomatosis, congenital heart disease (CHD), mediastinal masses, or chromosomal anomalies. Acquired chylothorax is most commonly associated with trauma during thoracic surgery for CHD or CDH, but can also occur secondary to increase in venous pressure in patients with venous thrombosis. Significant antenatal chylothorax accumulation can impair lung development and cause pulmonary hypoplasia. The rate of lymph drainage is about 1 mL/kg per hour, most of which is reabsorbed by lymphatic capillaries into the thoracic duct. Flow is increased by physical activity and by enteral feeding. Chylothorax is usually unilateral and more commonly affects the right side.

Clinical presentation is that of respiratory distress secondary to lung compression, pulmonary hypoplasia, or symptoms of the underlying pulmonary or cardiac disease. Significant loss of lymphatic fluid postnatally can result in malnutrition secondary to fatty acid, triglyceride and protein loss, and infection secondary to loss of immunoglobulins and lymphocytes. Physical examination is significant for decreased breath sounds on the affected side with shifting of the cardiac apex to the contralateral side. Chest radiograph shows pleural effusion, compression of the lung on the affected side, and displacement of the heart to the opposite side. Diagnosis is established by analysis of the pleural fluid. In babies with established feeding, chylothorax appears milky with opaque color; however, in nonfed neonates it is clear. Lymphatic fluid is rich in triglycerides (more than 1.1 mmol/L), protein, and cells (more than 1000 cells/μL) with more than 80% lymphocytes.

Treatment is mostly supportive while awaiting resolution of the effusion. Mechanical ventilation and drainage of the chylothorax might be needed in patients with large effusions, and nutritional support using total parenteral nutrition is essential. Feeding, once started, with formulas containing high percentage of medium chain triglycerides (MCTs) is recommended because lymphatics are not needed for MCT absorption. However, this approach does not appear to significantly reduce the triglyceride and fatty acid content of the fluid accumulating in the pleural space. Intravenous immunoglobulin administration should be considered in patients with recurrent infections, especially if hypogammaglobulinemia is present. In most cases spontaneous resolution occurs within 4 to 6 weeks. Several treatment strategies have been described for cases with persistent chylothorax, including pleurodesis, ligation of the thoracic duct, and pleuroperitoneal shunt. Whereas povidone-iodine pleurodesis has been used successfully in persistent chylothorax, it has also been associated with renal failure. There is growing evidence from uncontrolled case studies suggesting a markedly positive effect of somatostatins and in particular octreotide in the treatment of chylothorax with minimal side effects. In the absence of a controlled trial evaluating safety and efficacy, this therapy should be reserved for persistent and severe cases and not as first line of treatment.[60]

Congenital Cystic Pulmonary Malformations

Congenital cystic lung disease comprises a broad spectrum of rare but clinically significant developmental abnormalities, including congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration (BPS), bronchogenic cyst (BC), and congenital lobar emphysema (CLE). These lesions were originally thought to be separate entities. However, the description of coexistence of multiple lesions (bronchogenic cyst, CCAM, and extralobar BPS) in the same patient suggests a common embryologic origin for these malformations. Blood supply to early bronchial buds is provided by primitive systemic capillaries that regress as pulmonary arterial blood supply becomes dominant. Interruption of tracheobronchial and vascular development at different sites and during different stages of lung growth would determine the congenital lesion produced as well as its blood supply.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION

CCAM constitutes multiple different hamartomatous lesions arising from the abnormal branching of immature bronchial tree. The term *congenital pulmonary adenomatoid malformation* (CPAM) has been proposed to substitute for CCAM because only two types of CCAM are cystic. CCAM is the most common congenital cystic lung disease occurring in 1 in 25,000 to 30,000 live births and more commonly in males. It affects both lungs equally, and is most commonly unilobar with predilection to affecting lower lung lobes. Unlike BPS, it is connected with the tracheobronchial tree and has pulmonary blood supply (Table 44-6). Different classifications have been proposed for CCAM, including types 1-3 based on

TABLE 44–6 Characteristics of Congenital Cystic Adenomatoid Malformation Versus Bronchopulmonary Sequestration

	Congenital Cystic Adenomatoid Malformation	Bronchopulmonary Sequestration
Classification	Types 0-4, microcystic and macrocystic	Intralobar and extralobar
Connection to tracheobronchial tree	Yes	No
Systemic blood supply	No	Yes
Associated malformation	Common	Less common
Location	Either lower lobe	Left lower lobe
Malignant transformation	Yes	Yes
Spontaneous regression of antenatally diagnosed cases	11%	75%

histopathologic findings, expanded later to include types 0-4, and microcystic versus macrocystic based on gross anatomy and antenatal ultrasound appearance. Whereas the latter classification has poor correlation with histologic features, it has a much better prognostic value than the earlier classification with microcystic lesions (cysts less than 5 mm) having poorer prognosis than macrocystic lesions (greater than 5 mm). Type 1 CCAM is the most common (50% to 65%) and consists of large cysts surrounded by multiple small cysts and is rarely associated with congenital malformations. Type 2 (10% to 40%) consists of multiple small cysts (0.5 to 2 cm) and is associated with cardiac, renal, and chromosomal abnormalities, whereas type 3 (5% to 10%) consists of multiple smaller cysts (rarely more than 0.2 cm) or solid mass that is associated with significant risk of hydrops and polyhydramnios resulting from caval obstruction and cardiac compression secondary to mediastinal shift.[65]

Clinical presentation varies. Fifteen percent of CCAM patients are stillborn and have a high incidence of associated anomalies. Of liveborn infants, 80% present with respiratory distress in the neonatal period while less than 10% present after the first year of life with recurrent pneumonia, lung abscess, failure to thrive, pneumothorax, or malignancy. With the advancement of ultrasonography, more cases of CCAM have been diagnosed antenatally. Second trimester ultrasound can identify the presence of echogenic pulmonary masses with mediastinal shift, hydrops, or polyhydramnios; assess the size of the lung and evidence of hypoplasia; and diagnose associated malformations. Fetal echocardiogram might diagnose cardiac malformations as well as identify the origin of the blood supply. High-resolution ultrasonography or fetal MRI can differentiate CCAM from other lesions, including BPS, BC, congenital emphysema, CDH, or enteric duplication. The natural history of CCAM is variable. Up to 40% undergo rapid growth and enlargement causing compression of the adjacent lung and heart with mediastinal shift, cardiac failure, and hydrops, whereas 11% undergo spontaneous regression. Maximum CCAM growth is achieved by 28 weeks' gestation and decrease in size can start afterward. Most cases of spontaneous regression usually occur in type 3 lesions and are not limited to small or mild cases, infact, cases of CCAM associated with hydrops have been described to undergo spontaneous improvement and regression. These cases do not actually "disappear" but become isoechogenic with the adjacent lung tissue and cannot be differentiated by ultrasound or postnatal chest radiograph. However, fetal MRI or postnatal chest CT will identify these lesions (Fig. 44-58).

Despite reported cases of spontaneous resolution, the presence of hydrops in CCAM patients is the single most important poor prognostic factor associated with high mortality. Fetal surgery using thoracoamniotic shunting or open fetal surgery has been associated with 60% and 70% survival, respectively. (See also Chapter 11.) Patients who are not suitable for surgery might benefit from antenatal steroids which were shown to decrease the size of CCAM lesions. The EXIT procedure should be considered in patients with significant mediastinal shift and cardiac compression at time of delivery.[9]

There is consensus on the need for surgical excision in treating symptomatic CCAM patients. In most cases, lobectomy or segmental excision might be adequate. However, pneumonectomy or multiple excisions might be needed in multilobar or bilateral lesions. In hybrid cases with associated BPS, special attention to identify and ligate the systemic blood supply is needed. The treatment of asymptomatic patients continues to be controversial between expectant management versus elective resection. However, the majority opinion seems to favor elective resection at 2 to 6 months of age secondary to the associated later complications, including recurrent pneumonia and malignancy. Following successful resection, the long-term functional outcome of children with CCAM is excellent with no physical limitations or increased risk for infection, although RSV immunoglobulin prophylaxis is advised in these patients.[9]

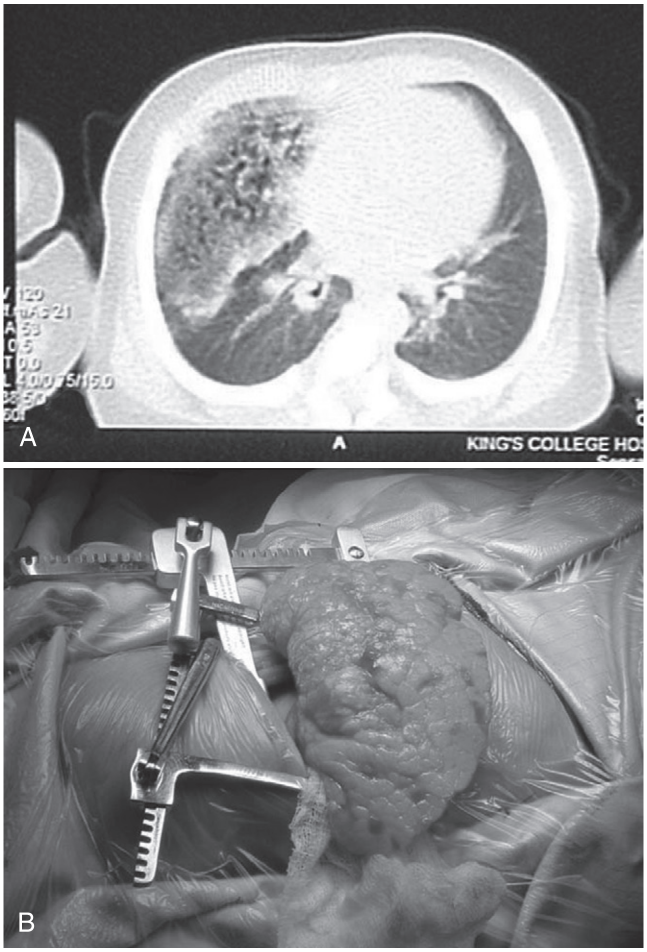

Figure 44–58. See color insert. **A**, Computed tomography scan showing right-sided microcystic congenital cystic adenomatoid malformation (CCAM). **B**, Lung resection of predominantly solid and small cysts (type 2) CCAM. *(Adapted from Stanton M, Davenport M: Management of congenital lung lesions,* Early Human Dev *82:289, 2006, with permission.)*

BRONCHOPULMONARY SEQUESTRATION

BPSs are microscopic cystic masses of nonfunctioning lung tissue that are usually supplied by the systemic circulation. The origin of sequestrations is believed to be an accessory lung bud that forms distal to the normal lung and migrates caudally with the esophagus. Two forms are recognized: intralobar sequestration (ILS) and extralobar sequestration (ELS). If the accessory bud arises before establishment of the pleura, it is contained within the normal lung (ILS); if it arises afterward, it has its own pleural covering and is completely separated from the normal lung (ELS). Like CCAM, sequestrations can be associated with multiple congenital malformations including chest wall, cardiac, gastrointestinal, and vertebral anomalies. ILS is usually asymptomatic in the neonatal period and can be diagnosed on routine antenatal ultrasonography. ELS can be asymptomatic or can present with pneumonia, atelectasis, bleeding, or high-output cardiac congestive heart failure secondary to the systemic arteriovenous blood shunting. Both forms are more common in the left lower chest and 10% of ELS are intra-abdominal. In 20% of patients with ELS, systemic blood supply originates from the infradiaphragmatic aorta. Large thoracic lesions can cause mediastinal shift and present with hydrops, although this presentation is very uncommon. Intra-abdominal ELS does not cause hydrops or pulmonary hypoplasia, although it may cause polyhydramnios secondary to gastrointestinal obstruction.[15]

On antenatal ultrasound, sequestrations appear as well-defined, echodense, homogeneous masses, and the diagnosis is confirmed by the documentation of systemic blood supply by color Doppler. If unclear, ultrafast MRI can establish the systemic blood supply, define the lesion, and identify other associated malformations. ELS can be differentiated from ILS if surrounded by pleural effusion. Intra-abdominal ELS appears as a suprarenal solid mass and should be differentiated from other suprarenal masses including neuroblastoma and mesoblastic nephroma. Antenatal or postnatal echocardiography can show associated cardiac malformation. BPS appears on chest radiograph as a posterior thoracic mass mostly on the left. Chest CT scan or even MRI might be needed to further delineate systemic blood supply.

Fetuses diagnosed antenatally with BPS should be delivered at a tertiary center where appropriate management of severe respiratory compromise and pulmonary hypertension is available. Following supportive care with appropriate respiratory management, symptomatic patients should be treated with surgical excision. However, this should be deferred until after stabilization in patients with severe PPHN. Up to 60% of right-sided ILS had anomalous pulmonary venous return, and accurate identification of arterial and venous supply is essential to prevent ligation of pulmonary vessels. Asymptomatic patients should undergo elective resection to prevent complications of malignancy or infection.[18]

Up to 75% of antenatally diagnosed BPS undergo spontaneous resolution. This is thought to be secondary to infarction associated with an overgrown blood supply or torsion, or due to decompression in the tracheobronchial tree. Untreated BPS cases associated with hydrops are uniformly fatal. Several fetal surgeries have been proposed including thoracoamniotic shunt for decompression of pleural effusion, surgical excision, or EXIT procedure.[18] Long-term complications of patients with resected BPS include gastroesophageal reflux disease, asthma, chest wall malformations, and pneumonia.

BRONCHOGENIC CYST

BCs consist mostly of a single cyst lined by respiratory epithelium and covered with elements of tracheobronchial tree including cartilage and smooth muscle. BCs originate from an abnormal budding of the ventral surface of the primitive foregut without undergoing further branching, resulting in a blind cyst that may or may not communicate with the airways. While cysts are mostly found centrally in the mediastinum, budding that starts late in gestation might originate from the distal airways generating peripheral cysts embedded within normal lung tissue. Potential locations for a BC include cervical, paratracheal, subcarinal, hilar, mediastinal, and intrapulmonary. Less common ectopic sites include paravertebral, paraesophageal, and pericardial locations.

In the neonatal period, most patients with BC are asymptomatic, and diagnosis is made on prenatal ultrasound or incidentally on a chest radiograph after birth. Symptoms, if present, are secondary to mass effect on airways, gastrointestinal tract, or the cardiovascular system. Even though major airway obstruction is uncommon, subcarinal lesions can present with severe obstruction. On the other hand, obstruction of smaller airways can cause air trapping, overdistention, and a clinical picture similar to that of congenital labor emphysema. Undiagnosed cases in the neonatal period usually present in older children or adults with pneumonia, hemoptysis, pneumothorax, dysphagia, or signs of caval obstruction.

Lesions diagnosed on prenatal ultrasound can be further differentiated from other cystic lesions by prenatal MRI. Postnatally, fluid-filled BCs can appear on chest radiograph as radiopaque areas. If connected to the airway, an air-fluid level may be seen. CT scan is the study of choice before undergoing surgery and provides a thorough characterization of the lesion and its relation to mediastinal structures.

Treatment of all cases of BCs is complete surgical excision. In symptomatic patients, this is performed after immediate clinical stabilization. Simple aspiration should be considered in patients with severe compromise as a temporizing measure, but complete resection is subsequently required. In asymptomatic newborns, surgery can be done electively at a few months of age. Patients who undergo resection of a BC have an excellent outcome. Life-threatening complications before surgery develop in a few patients who have a poor outcome. There are no long-term complications related to the resection of a BC.[43]

CONGENITAL LOBAR EMPHYSEMA

CLE is a rare anomaly of the lung that is characterized by postnatal overdistention of one or more segments or lobes of the lung. The mechanism underlying CLE is that of intrinsic or extrinsic obstruction of the airways causing air trapping, overdistention, and subsequent emphysema. Multiple mechanisms have been described to explain the development of CLE including dysplastic bronchial cartilage, inspissated mucus, aberrant cardiopulmonary vasculature, and infection. In half of the cases no underlying pathology is identified. The left upper lobe is most frequently affected (42%), followed by right middle lobe (35%) and the right upper lobe (21%). The lower lobes are involved in 1% of the cases. CLE is three times as common in males.

Patients usually present in the neonatal period with respiratory distress; however, later presentations have been described. The severity of the clinical picture depends on the size of the CLE and the degree of compression of the normal lung. Physical examination might be indistinguishable from pneumothorax with decreased air entry, bulging of the affected hemithorax, and in severe cases, shifting of the apical heartbeat to the contralateral side. CLE can be detected at midgestation using a combination of ultrasonography and ultrafast fetal MRI, although differentiation from CCAM might be difficult. Diagnosis is usually made by chest radiograph that may show an early opaque mass due to delayed clearance of lung fluid followed by a hyperlucent overexpanded area of lung with atelectasis of the adjacent lobes of the lung, depression of the diaphragm, and mediastinal shift to the opposite side (Fig. 44-59). The distinction of CLE from pneumothorax is essential to prevent attempted aspiration and potential development of tension pneumothorax. The presence of alveolar air markings throughout the emphysematous area is supportive of CLE. The emphysematous segment may also herniate anterior to the heart and great vessels. CT scan of the chest is a useful adjunct. Treatment of CLE depends on the severity of symptoms. Conservative and supportive management should be considered in milder cases. Surgical resection of the affected area should be considered in patients with life-threatening progressive pulmonary insufficiency from compression of the adjacent normal lung. Once the emphysematous area is resected, the long-term prognosis is excellent.[42]

Pulmonary Arteriovenous Malformation

Intrapulmonary arteriovenous malformation is a rare vascular anomaly of the lung that is associated with cyanosis and may lead to significant morbidity. It can be associated with skin hemangiomas and present with cyanosis not responding to medical management. Antenatal diagnosis of intrapulmonary arteriovenous malformations is possible and allows early treatment. Postnatal diagnosis is confirmed by angiography. Treatment is by surgical resection, although successful management with resolution of intrapulmonary shunting has been described using transcatheter occlusion with multiple coils.[38]

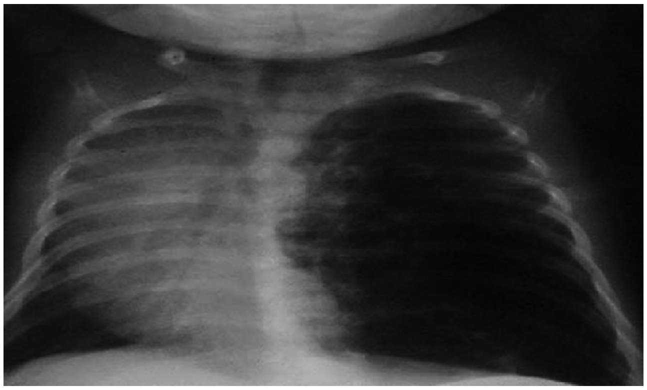

Figure 44–59. Congenital lobar emphysema with marked tracheal and mediastinal shift, in a patient who required emergency lobectomy. *(From Shanmugam G et al: Congenital lung malformations—antenatal and postnatal evaluation and management*, Eur J Cardiothorac Surg *27:45, 2005, with permission.)*

ACQUIRED NEONATAL PULMONARY DISEASES

Meconium Aspiration Syndrome

Meconium is comprised of desquamated fetal intestinal cells, bile acids, minerals, enzymes including alpha$_1$ antitrypsin and phospholipase A$_2$, as well as swallowed amniotic fluid, lanugo, skin cells, and vernix caseosa. Antenatal passage of fetal intestinal contents into the amniotic fluid is common at 15 weeks' gestation; however, the incidence decreases with increasing gestational age, and becoming very infrequent by 34 weeks' gestation.

Meconium staining of amniotic fluid (MSAF) occurs in 5% to 24% of normal pregnancies (mean 13%). Risk factors for MSAF include postmaturity (gestational age beyond 41 weeks), small for gestational age (SGA), fetal distress, and compromised in utero conditions including placental insufficiency and cord compression. The latter is evident by the observation that 20% to 30% of infants born through MSAF are depressed at birth with an Apgar score of 6 or less at 1 minute. The mechanisms underlying MSAF are not clear; however, there is evidence of increased parasympathetic activity causing increased peristalsis and relaxation of the anal sphincter secondary to enhanced vagal output during cord compression. Recently, corticotrophin releasing factor, a known mediator of colonic motility, has been implicated in the pathogenesis of hypoxia-induced MSAF in a rat model.[44]

Meconium aspiration syndrome (MAS) has been defined as respiratory distress in an infant born through MSAF whose symptoms cannot be otherwise explained. This definition correctly implies that respiratory distress might occur in infants born through MSAF for a variety of reasons other than MAS. Infants born through MSAF were found to have a 100-fold increase in the likelihood of developing respiratory distress than those born through clear amniotic fluid, even in those with normal fetal heart tracing and Apgar scores. MAS occurs in only 5% of patients born through MSAF, although the case-fatality rate of affected infants remains high at 5% to 40%. The incidence of MAS had decreased recently secondary to improved obstetric standards, especially secondary to a decrease in number of deliveries beyond 41 weeks' gestation in developed countries. Two large recent studies from the United States and Australia/New Zealand confirmed that the incidence of MAS increases with increasing GA for infants between 37 and 41 weeks in a study cohort involving more than 14 million babies. The incidence of MAS (USA) and MAS requiring intubation (AUS) in this cohort increased twofold to threefold at 41 weeks' gestation compared with neonates born at an earlier gestation.[21,73]

PATHOPHYSIOLOGY

During normal fetal breathing, pulmonary fluid moves predominately outward from the airways into the oropharynx. However, severe asphyxia in utero can induce gasping and aspiration of amniotic fluid and particulate matter into the large airways. The meconium inhaled by the fetus may be present in the trachea or larger bronchi at delivery. Meconium and squamous epithelium can also be found as far as the alveoli in stillborn infants, and it is widely recognized that meconium aspiration can occur antenatally. After air breathing has commenced, especially if accompanied by gasping respirations, there is a rapid distal migration of meconium within the lung. Thick meconium, nonreassuring fetal heart tracing, low Apgar score at 5 minutes, instrumental delivery, especially emergency cesarean section, and planned home delivery are associated with increased risk for development of MAS.[21,40] The presence of such risk factors in a depressed infant born through MSAF should alert the treating physicians that vigorous postnatal therapeutic intervention should be pursued.

The mechanisms involved in the development of MAS reflect the cumulative effect of aspiration of MSAF in an already compromised infant. Therefore, the underlying pathology is that of fetal compromise, discussed elsewhere, and pulmonary injury secondary to aspiration of meconium. Meconium aspiration causes injury to lung tissues through a variety of mechanisms including complete or partial obstruction of airways, sepsis, inflammation, complement activation and cytokine production, inhibition of surfactant synthesis and function, apoptosis of epithelial cells, and increased pulmonary vascular resistance (Fig. 44-60).

Aspiration of meconium particles can result in complete or partial obstruction of the airways. Complete obstruction causes collapse of the lung area distal to the obstruction and subsequent atelectasis. The effect of partial obstruction, however, has been traditionally thought of as a ball-valve effect, wherein air can enter during inspiration but is unable to escape during expiration. The resultant trapped air and overdistention increase the incidence of air leaks, including pneumothorax, which can occur in as many as 15% to 30% of affected infants.

The various components of meconium have been shown to induce inflammation and cytokine activation in different studies. Within hours, neutrophils and macrophages are found in the alveoli, larger airways, and the lung parenchyma. This is associated with activation of proinflammatory cytokines, tumor necrosis factor TNF-α, γ-interferon, and interleukins (IL) 1β, IL-6, and IL-8. Furthermore, meconium was found to activate the lectin and alternative complement pathways, and administration of complement 1 inhibitors efficiently reduced the level of these proinflammatory factors, thus adding a potential therapeutic target for the treatment of MAS.[61] Meconium has also been shown to cause apoptosis of pulmonary epithelial cells through a caspase-3 mechanism.

Meconium has been shown to decrease synthesis and activity of surfactant in in vitro and in vivo animal and human studies. The exact mechanism is not clear; however, bile acids and secretary phospholipase A_2, both of which are components of meconium, have been implicated. Meconium has also been shown to displace surfactant from the alveolar surface, decreasing its ability to decrease surface tension. Decreased surfactant availability might result in increased surface tension with atelectasis, decreased lung compliance and lung volume, and subsequent hypoxia.[35]

Severe persistent pulmonary hypertension often complicates cases of MAS. The mechanism of pulmonary vasoconstriction in these patients is not clear. Pulmonary artery vasoconstriction induced by fetal and neonatal hypoxia most likely play a major role. The direct effect of meconium on pulmonary vasculature is controversial. In vitro studies observed relaxation of tracheal and pulmonary vasculature smooth muscles in response to meconium exposure in rats. On the other hand, in vivo administration of meconium caused increased contractility of vascular and tracheal smooth muscles suggesting that meconium induces pulmonary vasoconstriction through lung release of pulmonary vasoconstrictor humoral factors. The potent vasoconstrictors thromboxane A_2 and angiotensin II, as well as cytokines, have been implicated in this mechanism.

CLINICAL FEATURES

The infant with MAS often exhibits the classic signs of postmaturity with evidence of weight loss, cracked skin, and long nails, together with heavy staining of nails, skin, and umbilical cord with a yellowish pigment. These infants often are depressed at birth. In fact, the initial clinical picture can be dominated by neurologic and respiratory depression secondary to the hypoxic insult precipitating the passage of meconium. Respiratory distress with cyanosis, grunting, flaring, retractions, and marked tachypnea soon ensues.

Characteristically, the chest acquires an overinflated appearance, and rales can be audible on auscultation. The chest radiograph shows coarse, irregular pulmonary densities with areas of diminished aeration or consolidation (Fig. 44-61). If such infiltrates are a manifestation of retained lung fluid, they would be expected to clear within 24 to 48 hours. Pneumothorax and pneumomediastinum are common in infants with severe MAS. Hyperinflation of the chest and flattening of the diaphragm secondary to air trapping are sometimes noted on chest radiograph. Cardiomegaly also might be detected, possibly as a manifestation of the underlying perinatal hypoxia.

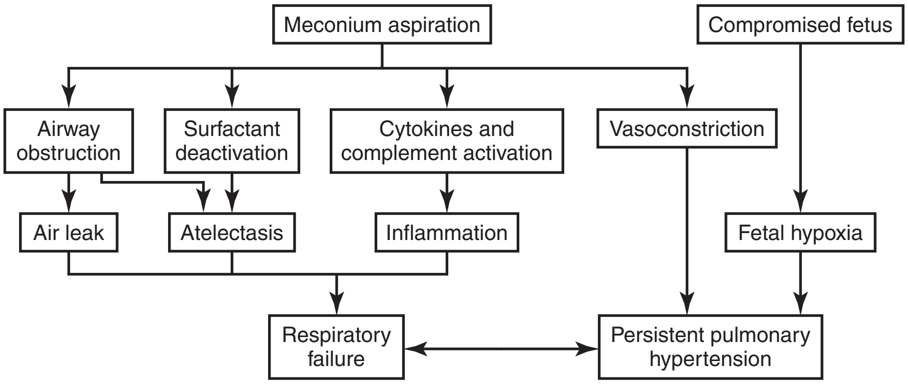

Figure 44–60. Pathophysiology of meconium aspiration syndrome.

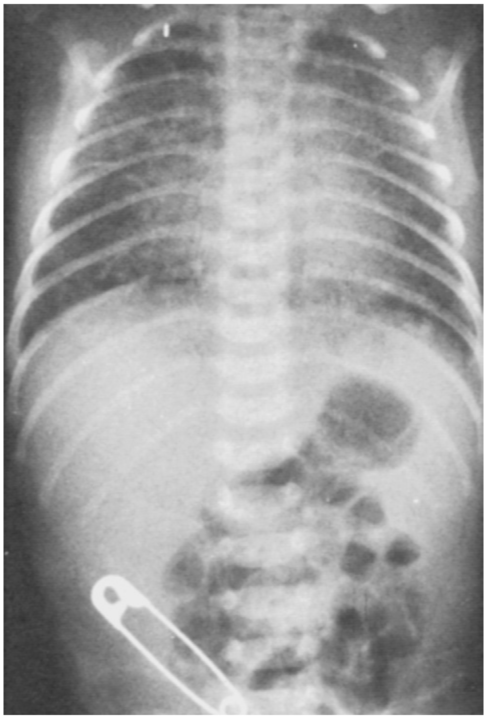

Figure 44–61. Chest radiograph showing multiple linear streaks of meconium aspiration pneumonia.

Arterial blood gases characteristically reveal hypoxemia with evidence of right-to-left shunting. Hyperventilation can result in respiratory alkalosis, although infants with severe disease usually have a combined respiratory and metabolic acidosis secondary to hypoxia and respiratory failure. One should be alert to the possible development of PPHN, which frequently accompanies MAS and can contribute substantially to morbidity.

MANAGEMENT

In the Delivery Room

Successful management of patients with MAS depends on close observation during and immediately following labor in at-risk mothers as well as aggressive intervention in newborns presenting with risk factors for developing MAS (Box 44-13). This requires a collaborative effort by the obstetric and neonatology teams. Because at-home delivery was associated with a threefold increased risk for MAS, mothers at risk, especially those who are postdate, should deliver in a facility where immediate medical intervention is available. Mothers at a gestational age of 41 weeks or greater with thick MSAF and nonreassuring fetal heart tracing require careful monitoring. Fetal scalp oximetry is a technique of fetal monitoring that might improve the accuracy of detecting newborns at risk. In fetuses with nonreassuring fetal heart rate patterns, fetal oxygen saturation below 30% had a high correlation with a scalp pH value of less than 7.2.[41] Infants born by emergency cesarean section, depressed neonates, and those with low 5-minute Apgar scores, are at very high risk for development of MAS and should be followed closely.

BOX 44–13 Management of Meconium Aspiration Syndrome

DELIVERY ROOM

Women at risk should deliver in a center where immediate neonatal care is available.
Meconium aspiration can develop in utero.
Amnioinfusion for meconium staining of amniotic fluid (MSAF) in the setting of standard peripartum surveillance is not routinely indicated.
Suctioning via endotracheal tube is indicated for depressed infants before stimulation.

NEONATAL INTENSIVE CARE UNIT

Surfactant administration may be beneficial.
Inhaled nitric oxide is indicated for associated persistent pulmonary hypertension.

UNRESOLVED ISSUES

The use of amnioinfusion for MSAF when routine surveillance is not available, such as in developing countries
Routine suctioning of the oropharynx at the perineum
The administration of surfactant as a bolus versus lavage
The utility of anti-inflammatory agents

Amnioinfusion refers to the instillation of normal saline or lactated Ringer's solution into the uterus through a catheter for the purpose of replacing amniotic fluid in cases of oligohydramnios and MSAF. Amnioinfusion might decrease the incidence of MAS by two mechanisms: diluting meconium consistency and decreasing cord compression, thereby resolving asphyxia and gasping. A meta-analysis of 13 studies demonstrated that the use of prophylactic intrapartum amnioinfusion for moderate or thick MSAF shows two distinct patterns. When standard peripartum and expert neonatal care are available, amnioinfusion does not improve outcome. In contrast, where antenatal and neonatal care are limited, such as underserved African communities, 75% of MAS is prevented. Furthermore, amnioinfusion decreased the frequency of cesarean section rate (OR, 0.74), meconium below the vocal cords (OR, 0.18), and neonatal acidemia (OR, 0.42) with no increase in the rate of chorioamnionitis (OR, 0.47).[56] A large, multicenter, randomized trial involving 1998 women concluded that in clinical settings with standard peripartum surveillance, amnioinfusion in the presence of thick MSAF did not reduce the risk of perinatal death, moderate or severe MAS, or other serious neonatal disorders.[27] This led the American College of Obstetricians and Gynecologists to issue an opinion statement: "Based on current literature, routine prophylactic amnioinfusion for the dilution of meconium-stained amniotic fluid should be done only in the setting of additional clinical trials. However, amnioinfusion remains a reasonable approach in the treatment of repetitive variable decelerations, regardless of amniotic fluid meconium status."[5]

Suctioning of the oropharynx upon delivery of the head and before delivery of the shoulders is used commonly in obstetric practices to decrease the possibility of meconium aspiration with the first breath. A multicenter, randomized, prospective study concluded that antepartum suctioning is not warranted and does not decrease the incidence of MAS even in high-risk infants. On the contrary, it may lead to added complications including bradycardia, desaturations, and increased incidence of pneumothorax.[68] In 2000, Wiswell and colleagues documented in a multicenter, randomized, international study that intratracheal suctioning did not decrease the incidence of MAS in vigorous neonates born through MSAF.[70] The Neonatal Resuscitation Program (NRP) shortly afterward implemented the policy of reserving tracheal intubation for only depressed infants. Vigorous infants defined as those with strong cry, normal heart rate, and good tone should not be intubated for MSAF regardless of how thick it is. Following dissemination of this policy, Kabbur and colleagues documented a significant decrease in the rate of delivery room intubation in infants born through MSAF without a change in overall respiratory complications supporting the efficacy of NRP recommendations.[36]

In the Neonatal Intensive Care Unit

Management of patients with MAS consists mainly of supportive respiratory and cardiovascular care. Maintaining normal blood pressure, adequate perfusion, and preventing hypoxia are essential in decreasing complications. The use of antibiotics is indicated until infection is ruled out since MSAF could be the first sign of fetal sepsis or pneumonia, which may be indistinguishable from MAS on chest x-ray examination. Ventilatory support is indicated in the presence of respiratory failure or persistent hypoxemia nonresponsive to high fractional inspired oxygen. There is no clear evidence or consensus of an advantage of one ventilatory strategy. However, in the presence of air leak or failure of conventional ventilation, HFOV should be considered in units familiar with this ventilatory strategy. $\mathrm{PaO_2}$ should be maintained at the high end of the recommended level (80 to 100 mm Hg) to minimize hypoxia-induced pulmonary vasoconstriction. Details of mechanical ventilation are discussed in Part 4.

Surfactant administration should be considered in severe cases of MAS. In a Cochrane review of available data, surfactant decreased the need for ECMO in patients with MAS (relative risk 0.64, 95% CI, 0.46, 0.91), and the number needed to treat to prevent one ECMO case was 6.[23] While surfactant administration in one study was associated with reduced hospital stay with a mean difference of 8 days, it did not affect mortality, days on ventilator or oxygen, BPD, pneumothorax, or pulmonary interstitial emphysema. The most effective method of delivering surfactant, bronchoalveolar lavage versus bolus administration, as well as which surfactant to use is controversial. In cases complicated by PPHN, iNO should be considered. ECMO can be life saving in patients with continued hypoxia despite aggressive treatment. In a recent review of the ECMO experience in the United Kingdom, MAS accounted for 48% of ECMO patients and was associated with 97% survival. Radhakrishnan and colleagues, in reviewing 4310 ECMO cases, noted a lower complication rate in MAS patients that required either venoarterial or venovenous ECMO than in non-MAS ECMO patients. They suggested that consideration should be made for more relaxed ECMO criteria in patients with MAS.[58]

Observational studies in infants with MAS showed some improvement of pulmonary function with the use of inhaled or systemic steroids. However, a Cochrane meta-analysis of data in 2003 concluded that there is insufficient evidence to assess the effects of steroid therapy in the management of MAS. Future directions for treatment of MAS aimed at reducing inflammation and cytokine production are promising. Multiple anti-inflammatory substances including aminophylline, Clara cell protein, monoclonal anti–mannose-binding lectin antibodies, caspase-3 inhibitor, and C1 complement inhibitor have shown some effect in animal models of MAS.

The ultimate prognosis depends not so much on the pulmonary disease as on the accompanying asphyxial insult and treatment required. No specific long-term deficits in pulmonary function have been attributed to this disorder, although BPD can result from prolonged assisted ventilation. Compromised infants born through MSAF have an increased incidence of acute otitis media, probably secondary to meconium contamination of the middle ear.

Other Aspiration Syndromes

Respiratory distress can develop in the newborn infant secondary to aspiration of other amniotic fluid material, including purulent amniotic fluid, vernix caseosa, and maternal blood. Small case reports have documented these entities. The clinical picture is that of respiratory distress as described above. X-ray findings can be indistinguishable from MAS, although lack of MSAF and other risk factors for MAS help in the diagnosis. Aspiration of maternal blood can be difficult to differentiate from pulmonary hemorrhage, especially if there is no history of antepartum hemorrhage. However, infants with pulmonary hemorrhage are usually sicker, with cardiovascular compromise including hypotension, poor perfusion, coagulopathy, and low platelets. Furthermore, the presence of swallowed blood in the stomach of affected infants suggests aspiration. Treatment with antibiotics is indicated if pneumonia is suspected secondary to aspiration of infected amniotic fluid.

Aspiration is most likely to be seen in preterm infants, those with disorders of swallowing, and infants with esophageal atresia and tracheoesophageal fistula. Small preterm infants are at greatest risk when fed excessive volumes per gavage or through misplaced orogastric tubes. These infants might initially present with cyanosis, desaturation, or apnea and subsequent respiratory distress, with pulmonary infiltrates visible on radiographs. The severity of disease varies; it can be indistinguishable from an inflammatory pneumonitis. Aspiration syndromes associated with disorders of swallowing may be suspected from the perinatal history (asphyxia), feeding history (cyanosis, excessive drooling, poor suck), and physical examination. The precise cause, however, might not be readily apparent, and these infants require extensive neurologic evaluation. Neonates with tracheostomies or gastrostomies are at risk for aspiration. Infants with recurrent aspiration, particularly those with disorders of the swallowing mechanism, present complex management problems.

Neonatal Pneumonia

Neonatal pneumonia continues to account for significant morbidity and mortality, especially in developing countries. Mortality has been found to be as high as 29 per 1000 live births in a rural area of India and as many as 800,000 neonatal deaths in developing countries have been attributed to acute respiratory infections according to World Health Organization estimates. However, in developed countries, the incidence varies between 1% in term neonates and 10% in ill infants with low birthweight. On the other hand, pneumonia was the cause of death in 50% of infants with extremely low birthweight in one series, and pneumonia was also diagnosed by the presence of inflammation in 15% to 38% of stillborn infants at autopsy.

ETIOLOGY

Neonatal pneumonia is classified as *early*, presenting before 3 days of life, and *late*, presenting after 3 days of life. Congenital pneumonia is one subset of early pneumonia that is acquired in utero and usually presents immediately after delivery. Congenital pneumonia is acquired through aspiration of infected amniotic fluid, ascending infection through intact or ruptured membranes, or hematogenous spread through the placenta. Early pneumonia can also be acquired during labor secondary to aspiration of infected amniotic fluid or bacteria colonizing the birth canal. Late neonatal pneumonia is usually a nosocomial infection and occurs most commonly in ventilated neonates, although infection through hematogenous spread can also occur.

Whereas bacterial, viral, and fungal agents can cause pneumonia, the etiologic agent is usually related to the timing of occurrence of pneumonia. Group B *Streptococcus* (GBS) is the most common cause of early pneumonia. However, the overall incidence of GBS sepsis has decreased dramatically since the introduction of universal screening and intrapartum antibiotic prophylaxis. The incidence of early GBS sepsis decreased by 33% between 2000 and 2003-2005 after the 2002 American Academy of Pediatrics (AAP) revised recommendations for universal screening for GBS colonization at 35 to 37 weeks. However, even though the overall incidence decreased to 0.33 per 1000 live births, the incidence increased in African American neonates from 0.52 to 0.89 per 1000 live births in the same time period. The etiology of this increase is not clearly understood. The contribution of African American race as an independent contributing factor persisted after correcting for socioeconomic differences.[14] The impact of the decreased incidence of GBS sepsis on the incidence of GBS pneumonia is not clear; however, the incidence of gram-negative sepsis, especially that caused by *Escherichia coli,* has increased following the implementation of the revised AAP guidelines.[12] Other bacterial causes of pneumonia include *Klebsiella, Enterobacter,* group A streptococci, *Staphylococcus,* and *Listeria monocytogenes.* Foul-smelling amniotic fluid is usually caused by anaerobes, but the contribution of these organisms to early-onset pneumonia is minimal. *Bacteroides* species occasionally is recovered.

Herpes simplex is the major cause of early viral pneumonia and is usually acquired during labor. Pneumonia is associated with 33% to 54% of disseminated herpes infection and is usually associated with high mortality rate. Other causes of early viral pneumonia include adenovirus, enterovirus, mumps, and rubella, whereas early pneumonia is an unusual presentation of congenital cytomegalovirus (CMV) infection. Other TORCH infections, including syphilis and toxoplasmosis, can also present with early-onset pneumonia. Up to 70% of disseminated candidal infections are associated with pneumonia, especially in premature infants.

Late-onset pneumonia is usually caused by organisms that colonize the newborn during the hospital stay. These include *Staphylococcus* species, including coagulase-negative staphylococci and *Staphylococcus aureus. Streptococcus pyogenes, Streptococcus pneumoniae, E. coli, Klebsiella, Serratia, Enterobacter cloacae, Pseudomonas, Bacillus cereus,* and *Citrobacter* can cause severe pneumonia especially in preterm infants. When *Chlamydia trachomatis* infection is acquired during labor, it usually manifests as pneumonia at 2 to 4 weeks of life because of its long incubation period. RSV is the most common viral agent causing late-onset pneumonia, although incidence and severity have decreased secondary to passive immunoprophylaxis. Other viral causes of late pneumonia include adenovirus, enteroviruses, parainfluenza, rhinoviruses, and influenza viruses and can result in severe disease. CMV pneumonia should always be considered in babies with congenital infection presenting with late respiratory decompensation. Prolonged courses of antibiotics and corticosteroids can increase the risk of candidal pneumonia, especially in colonized infants with extremely low birthweight.

CLINICAL PRESENTATION

Risk factors for early pneumonia are similar to those for neonatal sepsis and include prematurity, prolonged rupture of membranes, GBS colonization, chorioamnionitis, and intrapartum maternal fever. However, in one study, 22% of neonatal cases did not have risk factors, and in almost half, the only risk factor was early onset of labor. Therefore, risk factors should not determine whether to start antibiotics in neonates with respiratory distress, especially infants with extremely low birthweight. The presence and duration of mechanical ventilation and central venous lines were the main risk factors for development of late-onset pneumonia.[19] Other risk factors include abnormal neurologic conditions predisposing to aspiration pneumonia, poor nutrition, severe underlying disease, and prolonged hospitalization.

Clinical manifestations of early-onset pneumonia can be nonspecific; therefore a high index of suspicion should always be exercised. These symptoms include temperature instability, lethargy, apnea, tachycardia, metabolic acidosis, abdominal distention, poor feeding, and neurologic depression. Respiratory distress can present in the form of tachypnea and retractions in more than two thirds of affected neonates. Cough is an unusual symptom in neonatal pneumonia and was present in less than one third of neonates. Delay in diagnosis and treatment can lead to PPHN and septic shock.

Differential diagnosis for early neonatal pneumonia includes transient tachypnea of the newborn (TTN), RDS, MAS, and pulmonary congestion secondary to obstructed anomalous pulmonary venous return or other left heart obstructed lesions. Radiographic findings in pneumonia are nonspecific and thus do not help differentiate these disorders. Chest x-ray findings might include unilateral or bilateral streaky densities, confluent mottled opacified areas, or a diffusely granular appearance with air bronchograms. Differentiation from RDS is difficult in preterm infants, especially because preterm labor is a risk factor for pneumonia. Radiographic findings of TTN usually resolve by 48 hours and those of RDS are markedly improved after surfactant treatment, whereas radiologic changes of pneumonia may persist for weeks.

Late-onset pneumonia usually presents with nonspecific changes in the overall condition of the infant in the form of new-onset or increased apnea, abdominal distention or feeding intolerance, temperature instability, respiratory distress, hyperglycemia, or cardiovascular instability. Patients receiving ventilatory assistance usually present with an increased oxygen requirement or mechanical support.

The diagnosis of pneumonia requires a high index of suspicion in any infant with new onset of symptoms suggestive of sepsis. Sepsis workup, including blood culture, blood count, and differential should be obtained before starting antibiotics. The presence of elevated C-reactive protein, neutropenia, immature white blood cells, and thrombocytopenia is highly suggestive (although not diagnostic) of infection in newborn babies with risk factors. Tracheal Gram stain and culture should be considered in infants who require mechanical ventilation soon after intubation. A positive tracheal culture in the first 8 hours of life may correlate with a positive blood culture. After 8 hours, a positive tracheal culture might be secondary to colonization. Analysis and culture of pleural fluid, if present in adequate amount, can aid in the diagnosis in infants not responding to empirical therapy. Specific studies for viral or unusual bacterial infections should be obtained if suspected. Diagnosis of ventilator-associated pneumonia (VAP) can be troublesome, especially in preterm infants with underlying lung disease. Typically these infants' tracheas are colonized, discounting the validity of tracheal cultures. The Centers for Disease Control and Prevention has proposed stringent diagnostic criteria to diagnose VAP in infants younger than 1 year of age that relies on clinical symptoms of respiratory distress, hyperthermia, purulent tracheal secretions, increased requirement for ventilatory support, and new changes in chest radiograph that persist in at least two consecutive films.[26] However, the validity of these criteria in diagnosing VAP in preterm infants with underlying lung disease has not been substantiated. Further studies are clearly needed to better diagnose and treat pneumonia in ventilated infants with low birthweight.

MANAGEMENT

Successful treatment depends on identification of the causative organism, institution of early and adequate antibiotic therapy, and supportive care. Empirical antibiotic therapy is usually started before isolation of the organism. In early-onset pneumonia, ampicillin and gentamicin (dose based on gestational age and kidney function) are adequate initial therapy. However, with the increasing incidence of antibiotic-resistant gram-negative bacteria, this regimen may need to be altered based on specific institutional susceptibility data. Empirical therapy with vancomycin (for coagulase-negative staphylococci) and gentamicin is usually started for late-onset pneumonia. To decrease the possibility of developing vancomycin-resistant bacteria, an empirical regimen for late-onset sepsis/pneumonia may include nafcillin and gentamicin, and vancomycin is started once coagulase-negative *Staphylococcus* is identified or the clinical picture is deteriorating. In intubated infants, antibiotic coverage depends on the specific bacteria colonizing the trachea. Once the causative organism is isolated, specific therapy is started according to susceptibility profile. The duration of therapy is dependent on the causative organism and response to treatment; however, in uncomplicated pneumonia, 10 to 14 days of therapy is usually adequate.

Whereas antibiotic therapy is the mainstay of treatment, supportive care is essential and has been shown to decrease the mortality and morbidity associated with pneumonia in developing countries. In the acute stage, circulatory support with fluids and inotropes might be needed, and mechanical ventilation and oxygen should be administered to correct hypoxemia. Special attention to correct acidosis, hypoglycemia, and other possible electrolyte imbalance is also warranted. Parenteral nutrition with amino acids, carbohydrates, and lipids can provide adequate nutrition and prevent protein catabolism as well as amino and fatty acid deficiency. Feeding should be started as soon as possible to supply adequate calories. In the absence of respiratory distress or abdominal pathology with concern for aspiration, gavage feedings can be started.

Transient Tachypnea of the Newborn

Transient tachypnea is a common physiologic disorder of the newborn resulting from pulmonary edema secondary to inadequate or delayed clearance of fetal alveolar fluid. The initial clinical picture is usually completely resolved by 48 to 72 hours, hence the term *transient*. However, TTN continues to represent a diagnostic dilemma secondary to the inability to differentiate its initial presentation from that of other causes of respiratory distress. The incidence has been estimated at 5.7 per 1000 births in term infants. Risk factors for development of TTN include premature or elective cesarean delivery without labor. The incidence of pulmonary pathology including TTN was found to be twofold to threefold higher in infants born after planned cesarean delivery compared with a planned vaginal delivery. TTN is also more common in infants of diabetic mothers and mothers with asthma, although the mechanism of the latter association is not clear.

Fetal alveolar fluid is continuously secreted during pregnancy through an epithelial chloride secretion mechanism and the rate of secretion decreases a few days before delivery. At birth, the balance of fluid movement in the alveolus switches from chloride secretion to sodium absorption, causing resorption of intra-alveolar fluid. Sodium (Na), and thereafter water, absorption occurs in two steps; initially Na moves passively from the alveolar lumen into the cell by passive movement through a concentration gradient maintained by the Na-K-ATPase pump. Next, sodium is actively transported into the interstitium by amiloride-sensitive epithelial sodium channels (ENaC). Thereafter, the sodium and fluid are cleared through the lymphatic and vascular systems. The mechanisms underlying failure or delay in clearance of intra-alveolar fluid in patients with TTN are not totally clear and have been studied mostly in animals. The mechanical force of birth canal squeeze, originally thought to be the major factor in lung fluid resorption, is now believed to be a minor contributor. Immaturity of ENaC has been shown, both in animals and newborn babies, to impair fluid resorption, and as ENaC expression is developmentally regulated, this is especially relevant in the late preterm infant. Hormonal changes associated with spontaneous labor, especially surge of catecholamines and endogenous steroid, seem to be important in increasing the expression and activity of ENaC, which partially accounts for the higher incidence of TTN in elective cesarean section cases not preceded by spontaneous labor.[33] The clinical picture of patients with TTN is secondary to the decrease in lung compliance associated with pulmonary edema. Collapse of airways might also occur in response to fluid accumulation in the interstitium and peribronchial lymphatics. The net result is variable degrees of hypoxemia and respiratory acidosis.

Patients with TTN usually present very early after birth with symptoms of respiratory distress. Tachypnea is the most consistent finding, although increased work of breathing with expiratory grunting, nasal flaring, and retractions may also be present. Hypoxemia necessitating modest oxygen requirement (usually less than 40%), together with hypercapnia, can occur, while respiratory failure requiring CPAP is unusual. The most characteristic feature of TTN is the transient nature of this disease. In most patients, rapid continuous improvement in the clinical condition occurs within 24 to 48 hours of life, although in some patients symptoms might persist beyond 72 hours of life. Characteristic radiographic findings consist of perihilar streaking that represents engorgement of the periarterial lymphatics and fluid-filled interlobar fissures. Both the horizontal and oblique fissures can be affected although the horizontal is affected more commonly. Fluid-filled alveoli can present as fluffy bilateral infiltrates. Atelectasis and pleural effusion can also be seen. Although these radiographic changes can readily be distinguished from classic changes of RDS, TTN can conceivably accompany RDS in preterm infants. Radiographic changes are essentially resolved by 48 hours. Recently, Copettia and Cattarossi described a characteristic ultrasound finding in patients with TTN that they designated “double lung point.” This consisted of very compact comet-tail artifacts in the inferior fields of the lung that were rare in the superior fields.[17] This finding was not found in healthy newborns or those with other lung pathology. This finding, once substantiated, might help differentiate TTN from other disorders in equivocal cases. Differential diagnoses include RDS, pneumonia, MAS, and pulmonary edema of cardiac origin.

Treatment of TTN is supportive. However, because it is difficult to differentiate TTN from other disorders, most patients are usually started on antibiotics that can be discontinued after 48 hours if cultures are negative and the diagnosis is more clear. Lasix has no role in the treatment of TTN. Although not used in clinical practice to prevent TTN, antenatal steroids do enhance fluid resorption from alveolar spaces through increased transcription and activation of ENaC. Exogenous steroids or catecholamines do not seem to provide benefit after birth once the patient is symptomatic because recovery usually precedes the action of these agents. Delaying elective cesarean section until 39 to 40 weeks’ gestation or until spontaneous labor starts will decrease the incidence of TTN. However, this should be weighed against possible complications of delaying a needed cesarean section.[29] Although TTN is considered a self-limited transient condition, there are increasing data to suggest that TTN increases a newborn’s risk for developing a wheezing syndrome early in life.[47]

Pulmonary Hemorrhage

Pulmonary hemorrhage is a serious complication in neonates with RDS and has been associated with increasing risk for mortality and morbidity. Serious pulmonary hemorrhage has been defined as a gush of blood through an endotracheal tube in intubated neonates associated with a worsening clinical picture, requiring increased ventilatory support and blood product transfusion. The incidence of such severe hemorrhage is about 5% in very low birthweight infants and 10.2% in extremely low birthweight infants. Risk factors for development of pulmonary hemorrhage include extreme prematurity, surfactant administration, patent ductus arteriosus (PDA) with left to right shunting, multiple births, and male gender. Other risk factors include severe systemic illness, coagulopathy, and asphyxia. More than 80% of cases of serious pulmonary hemorrhage occur before 72 hours of life with a median of 40 hours; however, some babies might present after 1 week of life.[67]

The pathophysiology of pulmonary hemorrhage is believed to be secondary to sudden decrease in pulmonary vascular resistance, causing increased left-to-right shunting and pulmonary vascular engorgement, pulmonary edema, and ultimately rupture of pulmonary capillaries. This is especially true in patients with PDA after surfactant treatment. In post hoc analysis of patients enrolled in the trial for indomethacin prophylaxis in premature infants, a reduced risk for PDA accounted for 80% of the beneficial effect of prophylactic indomethacin on serious pulmonary bleeds.[6] However, pulmonary hemorrhage can also occur in patients who never received surfactant or had a PDA, highlighting the importance of other etiologies in the pathogenesis of pulmonary hemorrhage, including aggressive suctioning, especially using a closed circuit system.

Patients with pulmonary hemorrhage usually present with cyanosis, bradycardia, apnea, gasping, hypotension, increased work of breathing, hypoxia, and hypercapnia requiring increased ventilatory support. In almost one third of patients, serious pulmonary hemorrhage was preceded by prodromal episodes of suctioning frothy blood-tinged tracheal secretions. Chest radiographs demonstrate acute and varying degrees of worsening in underlying pulmonary disease, ranging from bilateral fluffy infiltrates to complete whiteout in severe cases.

Treatment of pulmonary hemorrhage is mostly supportive. Increased ventilatory support, especially positive end-expiratory pressure (PEEP), serves two purposes: It is needed for adequate ventilation and oxygenation, and it acts to tamponade and stop the bleeding. Suctioning should be limited during the acute hemorrhage. The efficacy of instillation of epinephrine, although used clinically, has not been proven in clinical trials. Transfusion of blood products and correction of underlying or secondary coagulopathy is essential. Pulmonary hemorrhage can cause deactivation of surfactant, and exogenous surfactant administration has been used successfully.[8] Prophylactic indomethacin decreased the incidence of pulmonary hemorrhage by 26% in infants with extremely low birthweight. Early recognition and treatment of PDA should be attempted in extremely premature neonates who are at the highest risk of mortality and morbidity associated with pulmonary hemorrhage. Pulmonary hemorrhage is associated with very high mortality approaching 50% in infants with extremely low birthweight. Whereas initial retrospective studies did not show worsening in neurodevelopmental outcome in survivors of pulmonary hemorrhage, a recent study showed increased incidence of cerebral palsy and cognitive delay (OR, 2.86 and 2.4, respectively).[6] Pulmonary hemorrhage was also associated with increased incidence of periventricular leukomalacia and seizures in survivors at 18 months of age.

Pulmonary Air Leak Syndromes

Air leak occurs more commonly in the newborn period than any other period of life. One percent to 2% of all live births were found to have pneumothorax on consecutive chest radiographs of term newborns in 1930. The incidence increases with decreasing gestational age. While the incidence was 6.3% in 1999 in very low birthweight infants in the Vermont-Oxford Network database, it approached 15% in those with a birthweight of 501 to 750 g.[32] Air leak syndromes include pneumothorax, pneumomediastinum, pulmonary interstitial emphysema, and pneumopericardium, and less commonly pneumoperitoneum and subcutaneous emphysema. Even though air leaks can occur spontaneously, they mostly occur in patients with lung pathology, including MAS, pneumonia, RDS, diaphragmatic hernia, and pulmonary hypoplasia, especially when positive pressure ventilation is required. The introduction of surfactant for treatment of RDS has caused a decrease in the incidence of air leaks. Conversely, the increasing practice of elective cesarean section before 39 completed weeks' gestation is associated with increased incidence of pneumothorax when compared with emergent cesarean section (OR, 4.2) or vaginal delivery (OR, 7.95).[72]

PATHOPHYSIOLOGY

Air leaks occur when overdistended alveoli rupture into the perivascular bundle, from where air tracks toward the hilum or pleura, causing pneumomediastinum or pneumothorax, respectively. In the preterm infant in whom the interstitium is more abundant and less dissectible, air can stay in the perivascular sheets causing pulmonary interstitial emphysema (PIE). Alveolar overdistention might occur in the presence of uneven alveolar ventilation or air trapping. Atelectasis in RDS and plugged small airways in MAS cause unequal distribution of the ventilated volume and transpulmonary pressure to the more distensible areas of the lung, increasing the risk of rupture and air leak. Partial obstruction during MAS causes air trapping when inspired air is not completely evacuated during exhalation. Further accumulation during subsequent breaths can rupture the alveolar space.

Different ventilatory strategies have been associated with the development of pneumothorax, including higher peak inspiratory pressure especially in the 24 hours preceding pneumothorax, long inspiratory time (greater than 0.5 seconds), and frequent suctioning in the 8 hours before pneumothorax. Elective initial use of high nasal CPAP (8 cm H_2O) in infants at 25 to 28 weeks' gestation was associated with increased incidence of air leak from 3% to 9% when compared with intubated infants who received surfactant therapy. However, there was no difference in the incidence of BPD or mortality rate between the two groups.[52] Recently, the use of CPAP (5 cm H_2O) in the delivery room in extremely low gestational age infants was associated with a decreased need for intubation and postnatal corticosteroids for BPD, and fewer days of mechanical ventilation when compared to initial intubation and surfactant administration within 1 hour after birth without an increase in the incidence of pneumothorax.[65b] Factors possibly associated with decreased incidence of pneumothorax include positive pressure ventilation (rate greater than 60) and volume-targeted ventilation. The use of HFOV following pneumothorax was associated with a decreased incidence of secondary pneumothorax.[51]

CLINICAL PICTURE

Even though pneumothorax can be the presenting diagnosis, more commonly it complicates underlying lung pathology. Sudden worsening in respiratory distress should always raise the suspicion of development of pneumothorax. Tachypnea, grunting, flaring, and retractions occur most commonly. Hypoxemia with cyanosis and increased oxygen requirement occur early in the course of pneumothorax while hypercapnia follows. Hypoxemia develops secondary to hypoventilation and ventilation-perfusion mismatch as the affected lung collapses. Physical examination reveals distant breath sounds, overdistention of the chest wall, and bulging abdomen on the affected side secondary to downward displacement of the diaphragm in patients with unilateral pneumothorax. The cardiac apex is displaced away from the affected side, as is the trachea.

Larger volumes of leaked air can cause significant increase in intrathoracic pressure, which impairs venous blood return and compromises cardiac output, causing poor tissue perfusion and metabolic acidosis. Although bradycardia and hypotension were not seen in a piglet model of moderate pneumothorax (30 mL of air), they can develop with a severe tension pneumothorax. The decreased cardiac output may cause a compensatory increase in carotid bloodflow as the body tries to protect vital organs. The resultant increase in cerebral bloodflow together with impairment of cerebral venous return secondary to increased central venous pressure might explain the increased incidence of intraventricular hemorrhage (IVH) in patients with pneumothorax.

Pneumomediastinum is often asymptomatic if not associated with pneumothorax and is mostly found on radiographic evaluation of patients with respiratory distress or distant heart sounds. Dissection of air through the anterior mediastinum into the neck can cause subcutaneous emphysema that is most commonly felt as subcutaneous crepitus in the face, neck, or supraclavicular notch area.

Pneumopericardium is a rare and serious complication probably caused by dissection of leaked air through the vascular bundle of great vessels. Trapped air in the limited pericardial space can quickly cause cardiac tamponade, decreasing venous return and cardiac output. Pneumopericardium should be suspected in patients with an air leak and sudden cardiovascular compromise associated with a narrow pulse pressure. The clinical picture consists of worsening respiratory distress, hypotension, bradycardia, pallor, and/or cyanosis. Cardiac sounds are distant or muffled on cardiac auscultation and a pericardial rub might also be heard. Low voltage QRS complexes can also be seen.

Pneumoperitoneum occurs when an intrathoracic air leak decompresses into the abdomen. It is typically asymptomatic and usually diagnosed on radiographic evaluation. It should, however, be differentiated from free abdominal air secondary to ruptured viscus in which patients are usually symptomatic with signs and symptoms of peritonitis.

DIAGNOSIS

In unstable neonates with progressive deterioration of the clinical picture, transillumination of the chest might provide a quick bedside diagnostic tool and allow for immediate intervention before x-ray confirmation. The technique involves the use of a fiberoptic light probe that is placed on the infant's chest wall while the nursery is darkened. In the presence of a large Pneumothorax, the entire hemithorax on the affected side lights up and the opposite side shows diminished transillumination because of lung compression on that side. In such cases, decompression should be accomplished without awaiting radiographic confirmation. However, in stable neonates, radiographic confirmation should always be sought before intervention. Inconclusive results or inexperience with the use of transillumination should also be confirmed by x-ray before intervention. This allows for proper localization of the pneumothorax, as well as excluding other disorders that do not need evacuation, such as pneumomediastinum, congenital emphysema, or diaphragmatic hernia.

The diagnosis is clear on radiographic evaluation of patients with a large or tension pneumothorax. Air accumulates between the parietal and visceral pleura, separating the lung from the chest wall and collapsing the ipsilateral lung. This can be seen as a curvilinear line silhouetting the collapsed lung (Fig. 44-62). External artifacts can also appear as a curvilinear line on chest radiograph; however, artifact can be differentiated from a pneumothorax by its tendency to extend beyond the chest cavity in either direction. In tension pneumothorax, the mediastinal structures, including the heart, are shifted away from the affected side. Lung collapse might not be complete despite a severe pneumothorax in patients with RDS secondary to poor compliance of the affected lung. Smaller pneumothoraces might appear as a small sliver of free air lateral to the lung or above the diaphragm causing the edge of the diaphragm or costophrenic angle to appear crisp. An anterior pneumothorax causes the affected lung to look translucent compared with the contralateral side. Confirmation of a small pneumothorax can be obtained with a lateral decubitus chest radiograph, where the unaffected side is dependent. As the free air rises, the reflection of the parietal pleura is seen clearly as a curvilinear line beyond which no lung markings are seen. This might also identify any contralateral pneumothorax or pneumomediastinum.

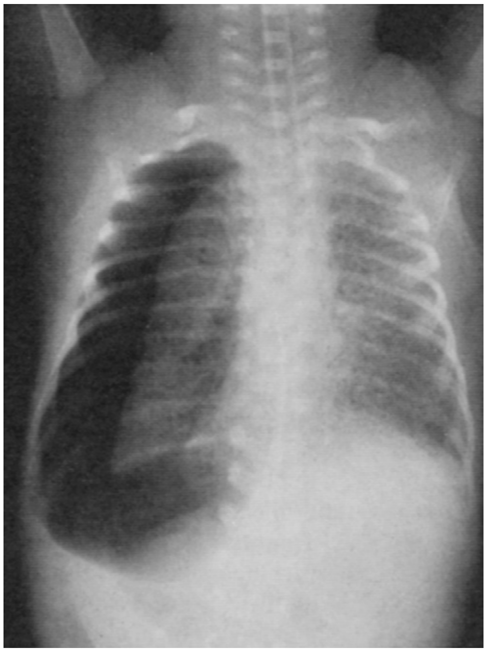

Figure 44–62. Tension pneumothorax on the right. An endotracheal tube is in place.

Pneumomediastinum can be diagnosed on chest radiograph by elevation of the edge of the thymus from the pericardium by mediastinal free air in a characteristic crescent or spinnaker sail configuration. A large pneumomediastinum can be differentiated from a pneumothorax by lateral decubitus radiographs as described earlier.

Pneumopericardium appears on plain chest radiograph as free air completely surrounding the heart, but not extending beyond the aorta or pulmonary artery into the upper mediastinum. Although difficult to differentiate from a large pneumomediastinum, the presence of air between the heart and diaphragm is diagnostic of pneumopericardium (Fig. 44-63).

PIE is seen on chest radiograph as coarse, nonbranching radiolucencies that project toward the periphery of the lung in a disorganized fashion. This appearance must not be confused with an air bronchogram, a classic radiographic sign of respiratory distress syndrome. Air bronchograms show long, smooth, branching radiolucencies that follow normal anatomic distributions similar to the bronchial tree. Pathologically, PIE is seen in lung tissues as multiple irregular, air-filled cysts varying in diameter from 1 mm to 1 cm, localized to interlobular septa, and extending radially from the hilum. PIE can be localized to one lung or a lobe of a lung, or can be diffuse bilateral disease. There is usually hyperinflation on the affected side that persists even after weaning of ventilatory support.

MANAGEMENT

Treatment of a pneumothorax depends on the severity of clinical presentation and whether it occurs during mechanical ventilation. In asymptomatic patients without underlying

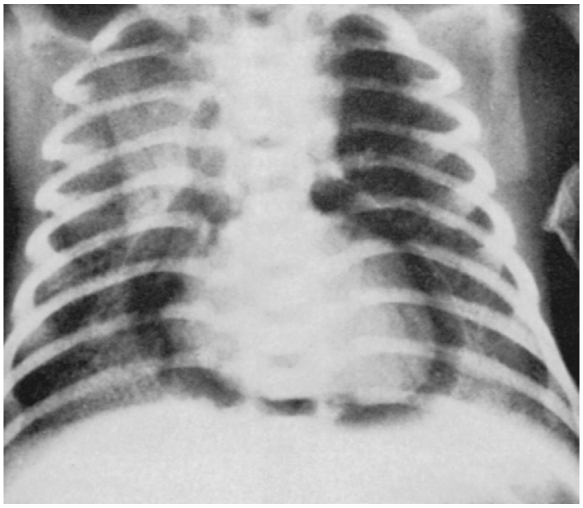

Figure 44–63. Pneumopericardium in a newborn.

pulmonary disease, no treatment is required; however, close observation for worsening pneumothorax and development of respiratory symptoms is clearly needed. The pneumothorax usually resolves spontaneously in 1 to 2 days. Follow-up radiographs can be obtained as mandated by the clinical picture. The association of symptomatic spontaneous pneumothorax with congenital renal malformations and the need for renal ultrasound evaluation in these patients is controversial. A review of 80 patients with spontaneous pneumothorax compared with normal controls showed no difference between the two groups in the rate of congenital renal malformations.[7]

Only supportive care is needed in the treatment of symptomatic patients with a mild pneumothorax without evidence of respiratory failure. While 100% oxygen given by a hood might lead to nitrogen washout and resolution or decrease in the size of the pneumothorax, this management strategy has not been adequately evaluated in infants. Oxygen is generally given only as needed to provide adequate oxgen saturations. Thoracocentesis is used for emergency evacuation of a large pneumothorax in unstable infants and might be the only treatment needed in nonventilated babies. However, recurrence of the pneumothorax should prompt the insertion of a chest tube. Thoracocentesis can also be used as a temporizing measure before chest tube insertion in ventilated infants.

In ventilated patients with a large or tension pneumothorax, the initial management is to wean PIP and PEEP to decrease further air leak while preparing for chest tube placement. Deciding on which brand of chest tube and which insertion technique to use depends most importantly on experience and comfort level. The tube should be inserted under complete aseptic technique and positioned anterior to the affected lung. This can be best achieved by starting in the anterior or middle axillary line. Position of the tube should be confirmed by anteroposterior and lateral chest radiographs. Once placed correctly, there is immediate improvement in oxygenation in affected patients, and the tube should be connected to an underwater seal with continuous suctioning at 10 to 20 cm H_2O. The chest tube should be secured once correct positioning is confirmed, with special attention given to prevent tension on the tube causing it to dislodge, particularly during radiologic examination. Chest tube insertion can be complicated by lung damage, which is usually diagnosed at autopsy, diaphragmatic paralysis secondary to phrenic nerve damage, or bleeding (Fig. 44-64). The use of a trocar or other sharp instrument during insertion should be avoided to decrease the chance of these complications. Once air bubbling stops, the chest tube should be clamped overnight, and if the pneumothorax does not reaccumulate, the tube can be successfully removed. Isolated pneumomediastinum is usually self-limiting and does not need intervention. These patients should be closely observed, however, because they might develop a pneumothorax.

Management of PIE can present a challenge. Increased support may lead to enlargement of the more compliant PIE cysts, which in turn compresses the relatively normal adjacent alveoli, causing worsening hypoxia and hypercapnia. The treatment strategy instead should target decreasing mean airway pressure while accepting higher CO_2 levels and oxygen requirement to allow for collapse of the dilated interstitial cystic lesions and expansion of the normal alveoli. HFOV is an acceptable ventilatory strategy for PIE because of the lack of inflating volumes that tend to worsen the PIE. In the case of failure of conservative management and persistent PIE, different treatment strategies have been tried, especially in unilateral cases, with varying degrees of success. These include single lung ventilation, rupture of the PIE into a pneumothorax that can then be evacuated by a chest tube, and resection of the affected side. Rastogi and colleagues described successful management of 15 of 17 neonates with unilateral PIE who failed conservative management with single-lung ventilation.[59]

The occurrence of air leak is associated with increased incidence of mortality and morbidity. Together with the increased incidence of IVH mentioned earlier, very low birthweight infants who develop pneumothorax in the first 24 hours of life were 13 times more likely to die or develop bronchopulmonary dysplasia. Furthermore, extremely low birthweight infants with a pneumothorax who had a normal head ultrasound were more likely to develop cerebral palsy after controlling for other factors (OR, 2.3).[45] Therefore, management strategies directed at avoiding the development of a pneumothorax should always be sought, including using minimal effective inspiratory pressures, low inspiratory time, high-frequency positive pressure ventilation, volume-targeted ventilation, early administration of surfactant in eligible patients, and rapid weaning of mechanical ventilation.

RIB CAGE ABNORMALITIES

Thoracic cage and skeletal abnormalities are a rare group of conditions that can cause respiratory distress by restriction of thoracic volume. They include a number of entities incompatible with life. In this group of diseases are those with hypoplasia of the ribs and thorax, including asphyxiating thoracic dystrophy (Jeune syndrome), thanatophoric dwarfism, achondrogenesis, homozygous achondroplasia, osteogenesis imperfecta (severe form), Ellis-van Creveld syndrome (chondroectodermal dysplasia), hypophosphatasia, spondylothoracic dysplasia, and rib-gap syndrome.

Respiratory distress caused by structural abnormalities of the chest wall should be readily apparent. However, marked narrowing of the thorax can result in what appears to be a distended abdomen, and the respiratory problem can be erroneously attributed to an intra-abdominal pathologic condition. The presence of other associated anomalies, for example, short-limbed dwarfism, together with close observation of respiratory excursions, examination of the bony thorax, and measurement of the circumference of the chest, establishes the diagnosis even before a review is made of the thoracic and skeletal radiographs.

With structural abnormalities of the chest wall, asphyxia and respiratory distress are present from birth. The infants are cyanotic and tachypneic and demonstrate severe retractions and characteristically a virtually immobile chest. Diaphragmatic excursions are prominent; thus, respiration appears entirely abdominal. Pulmonary hypoplasia accompanies the thoracic dystrophy, and radiographically the lungs can appear airless.

Infants with asphyxiating thoracic dystrophy, thanatophoric dwarfism, achondrogenesis, homozygous achondroplasia, or Ellis-van Creveld syndrome have thoracic radiographs with a squared-off appearance, and the posterior rib arcs all appear to be the same length. The clavicles appear very high, and the diaphragms are low (Fig. 44-65). The transverse diameter of the thorax can appear diminished in comparison with the vertical diameter. On a lateral view, the ribs are very short and can appear clubbed anteriorly. The anteroposterior diameter of the thorax is decreased.

The lungs may be poorly aerated, infiltrates are often present, and the heart might appear enlarged. Differentiating among the various syndromes of thoracic cage and skeletal abnormalities usually is accomplished by means of a skeletal survey. Multiple fractures and bone demineralization are characteristic of osteogenesis imperfecta and hypophosphatasia.

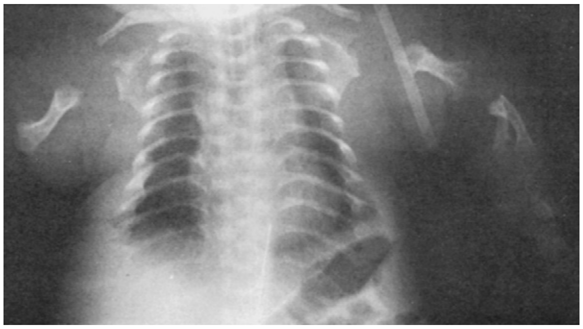

Figure 44–65. Radiographic appearance in thanatophoric dwarfism showing the narrow thorax, low diaphragm, and foreshortened humeri.

Asphyxiating Thoracic Dystrophy

The hallmarks of asphyxiating thoracic dystrophy are extreme constriction and narrowing of the thorax, short ribs, and short-limbed dwarfism, with abnormalities of the bones of the pelvis and extremities. Associated anomalies include polydactyly and deformed teeth. Renal abnormalities may be present, and renal failure can occur later. The syndrome is inherited as an autosomal recessive trait. As mentioned previously, the chest appears narrow and the sternum is prominent. The thorax is relatively immobile, and the ribs are horizontally directed and short with bulbous ends. In addition to the thoracic abnormalities, the infants have trident iliac bones with a double-notch appearance of the acetabulum.

Thanatophoric Dwarfism

Thanatophoric dwarfism (see Chapter 29) was differentiated from achondroplasia in 1967. The disorder has been generally fatal in the perinatal period with rare exceptions and probably is the most common form of lethal neonatal dwarfism. Appearance at birth is characteristic and includes striking micromelia in association with a normal trunk, a large head, and a narrow thorax. The radiographic findings include severely flattened vertebral bodies with markedly widened intervertebral disc spaces, small iliac rings, and flaring of the metaphyses of the long bones. There is a high incidence of polyhydramnios, and the infants often present in the breech position. The condition is inherited as an autosomal recessive trait, occurring more frequently in the African American population.

Infants present at birth with severe pulmonary insufficiency, requiring mechanical ventilation and intensive neonatal care. Because there is no prognosis for mental and physical development, immediate and accurate diagnosis is important in guiding medical decisions about continuation of support.

PHRENIC NERVE INJURY PARALYSIS

Phrenic nerve injury with paralysis of the diaphragm is an unusual cause of respiratory distress. It is most commonly present on the right side following birth trauma; thus an associated brachial plexus injury or Horner syndrome can coexist in approximately 75% of the patients. However, injury can also occur after cardiovascular or thoracic surgeries or following invasive procedures. The injuries are observed in infants who are large for gestational age, especially following shoulder dystocia or difficult breech extractions. Fractures of the humerus or clavicle are often observed. The nerve roots of C3 to C5 are stretched, with lateral hyperextension and traction on the neck. Recovery depends on the degree of injury; avulsion results in permanent injury, and diaphragmatic eventration secondary to muscle atrophy ensues. Lesser injury or edema of the nerve roots results in a spectrum of respiratory symptoms, which can include cyanosis, weak cry, tachypnea, or apnea; decreased movement is noted on the affected side. On radiographic examination, the involved hemidiaphragm is elevated, and atelectasis usually is observed on that side. The heart and mediastinum are shifted away from the affected side (Fig. 44-66). Ultrasonographic or fluoroscopic evaluation should be diagnostic and reveal paradoxical movement of the diaphragm with elevation during inspiration and descent with expiration. Congenital eventration of the diaphragm also results in an elevated hemidiaphragm with paradoxical movement. Secondary pneumonia is the major source of morbidity and mortality. Treatment of phrenic nerve palsy initially is supportive and, in the absence of avulsion, spontaneous resolution is to be expected. Surgical plication of the diaphragm might be required for selected infants with avulsion.

PART 6

Upper Airway Lesions

Robert C. Sprecher and James E. Arnold

A spectrum of pathologic conditions can affect the neonatal upper airway, resulting in respiratory distress at birth or within the first few weeks of life. The clinical presentations of these disorders, however, are often quite similar. The most common symptom is stridor; other signs and symptoms include cyanosis, apnea, dyspnea, retractions, hypercapnia, difficulty feeding, abnormal cry, and cough. The physician's ability to arrive at a diagnosis and treatment plan in the neonate with respiratory distress requires an understanding of the unique anatomic and physiologic factors that affect neonatal upper airway physiology. Of primary importance in evaluating the neonatal airway is determining the degree of emergency and the need to establish an artificial airway (endotracheal intubation or tracheostomy).

The evaluation of an infant with a suspected airway problem should encompass the entire upper airway, from the anterior nasal vestibule to the tracheal bifurcation. Obstruction at any level can lead to respiratory distress. The duration and severity of the infant's symptoms and the progressive nature of the airway distress direct the examiner to either a congenital or acquired disorder. Division of the neonatal upper airway into four primary physiologic components—nasal, oral, laryngeal, and tracheal—allows orderly discussion of the pathologic conditions that could afflict the newborn infant's airway.

NASAL AND NASOPHARYNGEAL LESIONS

Pyriform Aperture Stenosis

Anterior nasal stenosis can occur as the result of bony overgrowth of the nasal process of the maxilla. The diagnosis can be confirmed with computed tomography (CT) scanning. In most patients, conservative therapy with judicious use of intranasal and systemic steroids to reduce mucosal edema provides symptomatic relief. In severe cases, the infants present with significant nasal obstruction similar to those with posterior choanal atresia. Rarely, surgical intervention involving drill-out of the bony pyriform aperture through a sublabial approach is necessary.[4]

Nasolacrimal Duct Cysts

Nasolacrimal duct cysts can occur either unilaterally or bilaterally. Children present with varying degrees of nasal obstruction. Often there is associated epiphora. Intranasal examination shows a smooth, mucosa-covered mass under the inferior turbinate. The diagnosis is confirmed with CT scanning (Fig. 44-67). Surgery is usually required to eliminate the nasal obstruction. Often, simply marsupializing the cyst results in complete resolution. This can be accomplished with a cup forceps or the CO_2 laser.

Choanal Atresia

Neonates are preferential nasal breathers for the first 4 to 6 weeks of life. The entire length of the neonate's tongue is in close proximity to the hard and soft palate, which creates a vacuum and resultant respiratory distress when nasal obstruction is present. Bilateral choanal atresia is the most common cause of complete nasal obstruction in the neonate,

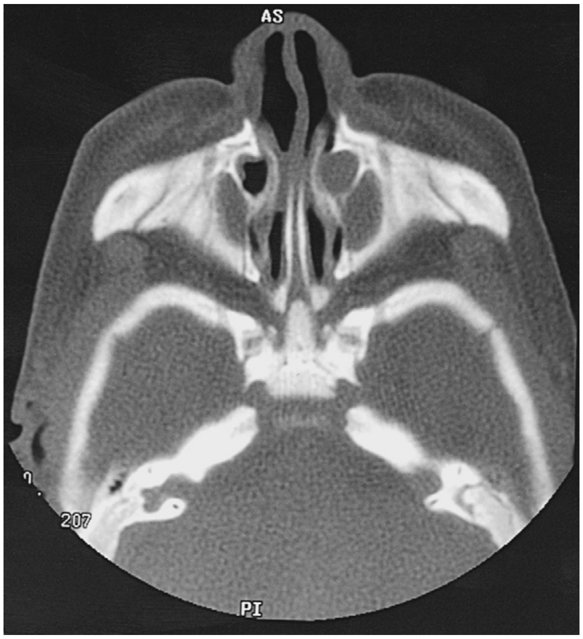

Figure 44–67. Bilateral nasolacrimal duct cysts causing complete anterior nasal obstruction.

occurring in approximately 1 in 7000 live births.[11] Associated anomalies occur in 20% to 50% of infants with choanal atresia.[29] The CHARGE syndrome includes *c*oloboma or other ophthalmic anomalies, *h*eart defect, *a*tresia choanae, *r*estriction of growth and developmental, *g*enital hypoplasia, and *e*ar anomalies with hearing loss.[8] Mutations in the *CHD7* gene (member of the chromodomain helicase DNA-binding protein family) located in chromosome 8q12 have been detected in more than two thirds of patients with CHARGE syndrome.[17,20] Recent data suggest overlap between CHARGE syndrome and 22q11.2 deletion syndrome in immunodeficiency states and hypocalcemia.[18] Children with CHARGE syndrome require intensive medical management as well as numerous surgical interventions. They also need multidisciplinary follow-up. A complete evaluation to rule out associated anomalies is therefore mandatory in all infants with bilateral choanal atresia.

Although bilateral obstruction always produces symptoms in the neonatal period, the degree of distress and cyanosis vary from severe asphyxia to cyanosis only with sucking. Typically, the infant has a history of distress when resting that is relieved with agitation and crying.

In a suspected case of choanal atresia, an attempt should be made to pass a 6-French catheter into the nasopharynx. Failure of the catheter to pass suggests choanal atresia. CT scan is required to differentiate between stenosis and atresia and to determine whether the atretic plate is bony or membranous.

Treatment of choanal atresia depends on the severity of the obstruction and the clinical presentation of the infant. Unilateral atresia rarely requires surgical intervention during infancy and is usually corrected before the child begins school (4 to 5 years of age). Bilateral atresia is usually repaired within the first few days of life. Historically, this was performed transpalatally, but today it is most commonly performed endoscopically through a transnasal route. Stenting of the repair has been associated with a higher rate of restenosis. As a result, single-stage repair is preferable.[36] Postoperatively, these patients do quite well, although repeated dilations may be necessary during the first year of life to maintain choanal patency. In CHARGE patients, tracheostomy may be preferable to immediate repair, depending on the severity of the associated anomalies.[1]

Intranasal Tumors

In addition to anomalous nasal development, nasal obstruction with airway distress can result from intranasal tumors such as dermoids, gliomas, encephaloceles, or teratomas. Any infant with an intranasal mass should be fully evaluated, including magnetic resonance imaging (MRI) to assess for skull base involvement and intracranial extension before intervention is undertaken. Biopsy of an unsuspected nasal encephalocele can lead to cerebrospinal fluid leak, meningitis, and death.

Gliomas and encephaloceles are rare lesions of neurogenic origin containing glial tissue. Gliomas are benign but locally aggressive tumors that are usually noticeable at birth or during early infancy. Approximately 15% of gliomas have a fibrous stalk with connection to the subarachnoid space.[14] Failure to recognize the fibrous stalk can lead to incomplete resection and tumor recurrence. Encephaloceles maintain their intracranial communication, with herniated brain tissue, dura, and cerebrospinal fluid constituting the tumor. Early surgical resection is generally recommended to alleviate the risk of meningitis that accompanies these tumors. In addition, progressive growth of the lesion can result in marked nasal deformity.

Teratomas are composed of multiple heterotopic tissues that are foreign to the site from which they arise. The etiology of these tumors is unknown, although they are believed to arise from rests of pluripotential cells sequestered during embryogenesis. The occurrence of nasopharyngeal teratomas is unusual, but when present they may be associated with significant airway distress.[5,7]

Generally, four classifications of teratomas are described. Dermoids are the most common subtype and are composed of epidermal and mesodermal elements. Teratoid tumors are composed of all three germ layers but are incompletely organized, whereas true teratomas are composed of all three germ layers with recognizable early organ differentiation. Epignathi are highly differentiated tumors and are rarely compatible with life.

Treatment of the nasopharyngeal teratoma involves airway stabilization and complete surgical resection. Prognosis is generally excellent with complete excision. Mortality in infants with teratomas is generally the result of airway obstruction.

Mucosal Obstruction

Generalized mucosal hypertrophy or edema can result in significant anterior nasal congestion and symptomatic obstruction in the neonate until oral breathing becomes reflexive. Treatment of these patients is generally conservative and includes humidification, saline drops, and judicious suctioning. Excessive attempts at suctioning can result in increased edema and exacerbation of the infant's symptoms. Gastroesophageal reflux may reach the level of the nasopharynx and can exacerbate nasal obstruction as well. Appropriate treatment of reflux may improve the nasal airway. Intranasal steroid drops might be helpful during periods of increased congestion such as that associated with viral rhinitis. Prolonged use of intranasal decongestants could lead to rhinitis medicamentosa (paradoxical mucosal swelling) and should be avoided.

Continuous Positive Airway Pressure Trauma

Care must be taken with the use of continuous positive airway pressure (CPAP) nasal prongs and masks in the neonate because nasal trauma can occur. Injuries such as excoriation of the nasal septum, necrosis of the columella, and lacerations of the nasal ala have been reported.[30] To prevent such injuries, nasal CPAP should be terminated as soon as possible. If injury is imminent and discontinuation of nasal CPAP is not possible, then changing to a different style of delivery may be useful.

ORAL AND OROPHARYNGEAL LESIONS

Normal oral cavity and oropharyngeal development is critical in establishing a patent upper airway. A variety of congenital anomalies have a known association with retrognathia, glossoptosis, and posterior tongue displacement and subsequent airway obstruction. Pierre Robin sequence,[11,34] Treacher Collins syndrome, Goldenhar syndrome (oculoauriculovertebral dysplasia), Crouzon disease (Fig. 44-68), and Down syndrome are the most common congenital anomalies that have oropharyngeal airway obstruction as an important clinical feature (see Part 5 of this chapter and Chapter 29).

In most of these patients, normal growth and development results in an increase in oropharyngeal space and a decrease in obstructive symptoms. Any treatment plan for these patients must take into consideration the knowledge that normal growth alleviates much of the obstructive pathology. Often, placing the infant in a prone position with slight head elevation during sleep dramatically decreases the degree of symptomatic obstruction. A modified nipple (McGovern nipple) that maintains oral patency or the placement of a soft nasal trumpet may be sufficient to achieve adequate airway patency until growth of the mandible occurs. Nasal CPAP is a noninvasive means of establishing a patent upper airway in patients whose obstruction is primarily manifested as obstructive sleep apnea.[3]

In severe cases, surgical intervention may be necessary. Tracheostomy has been the mainstay of surgical management of patients with upper airway obstruction, but pediatric mandibular distraction osteogenesis has been successful in lengthening the mandible of patients with significant retrognathia. Bilateral internal microdistraction can avoid tracheostomy in selected infants, and it can facilitate decannulation in those with a preexistent tracheostomy.[16,28,31]

Lymphatic Malformations

Lesions of the floor of the mouth or base of the tongue that cause posterior tongue displacement also can be associated with secondary airway obstruction. Lymphatic malformations are known to infiltrate the soft tissue of the floor of the mouth and cause significant upper airway obstruction. Lymphatic abnormalities appear as persistent clusters of thin-walled vesicles, usually filled with clear, colorless fluid. Tissues affected by lymphatic anomalies are notorious for the speed at which infection can spread through them.[35] At the first signs of inflammation, aggressive antimicrobial therapy is mandatory. Such infections may be life threatening, especially if inflammation leads to increased airway obstruction.

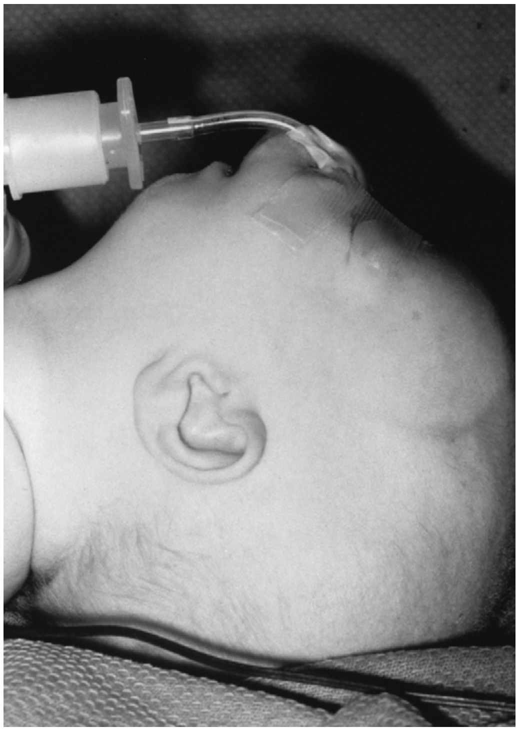

Figure 44–68. Crouzon disease: severe retrognathia with upper airway obstruction.

Because of the infiltrative nature of these lesions in the oral cavity, extensive lymphatic anomalies are often not amenable to surgical excision. Serial resection is ineffective in most instances and could in fact exacerbate the degree of oropharyngeal obstruction. Spontaneous resolution is uncommon. For macrocystic cervicofacial lymphatic malformations, the immunostimulant OK-432 (Picibanil) has been shown to be effective.[33] Tracheostomy is the treatment of choice for patients with a large oral cavity and oropharyngeal lymphatic malformations and associated airway obstruction.

Tongue Cysts

Cysts of the base of the tongue are a rare but serious cause of airway obstruction in the newborn infant (Fig. 44-69). An acute airway crisis could appear shortly after birth or several months later. A 43% mortality rate has been reported in the literature, with most deaths attributed to delayed diagnosis and acute airway obstruction. In most patients, these cysts represent thyroglossal duct remnants that arise from the foramen cecum.[19]

Dermoid cysts have been reported in the literature as tongue lesions associated with airway obstruction in the young infant. In contrast with the infant with a thyroglossal duct cyst at the base of the tongue, oral dermoids have a more insidious onset of symptoms, with presentation after 6 months of age.[9] Airway obstruction is in part caused by the mass effect in the hypopharynx and inferoposterior displacement of the epiglottis, which causes supraglottic obstruction.

Surgical excision is the treatment of choice in these patients. Marsupialization may be an option for the large cyst that is not amenable to complete resection. Significant tongue

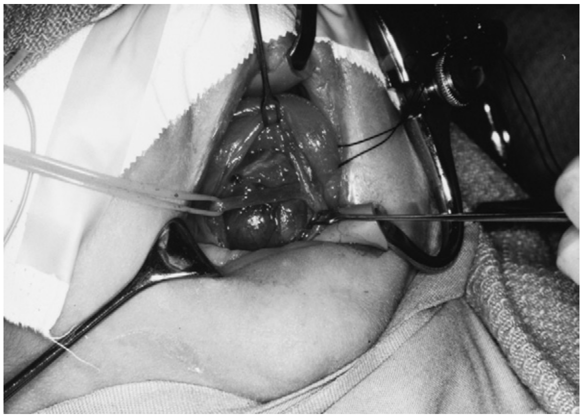

Figure 44–69. Oral cavity cyst.

swelling can develop postoperatively, and temporary intubation may be necessary to ensure a protected upper airway.

LARYNGEAL LESIONS

Embryologically, the larynx has three primary functions: airway protection, respiratory modulation, and voice production. The neonatal larynx has unique features, compared with that of an adult, that affect its ability to perform these three primary functions both in the normal and the diseased state.

Although the neonatal larynx is less than one-third the size of the adult larynx, the arytenoid cartilages are adult size at birth. This relationship between the supraglottic structures and the laryngeal inlet can contribute to the development of laryngomalacia in some infants. The subglottis is the smallest component of the pediatric larynx, whereas in the adult the glottic aperture is the size-limiting factor. The development of subglottic stenosis in the infant following endotracheal intubation is directly related to the small size of the subglottic opening.

In addition to differences in size, the infant larynx differs in its position in the neck relative to the cervical and facial skeleton. At birth the larynx may be found at approximately the level of the C4 vertebra. As the child grows, the larynx begins its inferior descent, ultimately resting at the level of C7. The high location of the larynx in the infant provides some protection against external trauma.

The cephalad location of the larynx also provides additional protection to the lower airway of the neonate, who has not yet fully developed the necessary protective reflexes to prevent aspiration during swallowing. In the young infant, the epiglottis rests on the nasopharyngeal surface of the soft palate. This position allows the infant to suckle without danger of aspiration and to breathe with the mouth closed.

Anatomically, the larynx may be subdivided into three components: supraglottis, glottis, and subglottis (Fig. 44-70). Disorders in one of these components produce a unique set of symptoms that allows the physician to begin narrowing the field of possible causes of airway distress in the infant. An attempt should be made to characterize stridor, when present, as inspiratory, expiratory, or biphasic.

Although not uniformly true, the level of obstruction is often reflected in the character of the stridor. Supraglottic lesions tend to produce a coarse, inspiratory stridor, whereas glottic and subglottic disorders are more “musical” in quality and often biphasic in nature. Pure tracheal lesions often manifest with a prolonged expiratory phase and expiratory stridor. Changes in the quality of the stridor with the level of activity and position of the infant are also a crucial aspect of the history. The quality of the child’s cry (normal, weak, or aphonic) can direct one to a glottic lesion, although severe subglottic narrowing could produce an abnormal cry due to limited air movement.

The presence or absence of cough should be documented. A feeding history is critical. Symptoms of aspiration or cyanosis with feeds can signal a specific disorder. Failure to thrive or other signs of systemic illness could indicate a more chronic disorder. The infant’s prenatal and perinatal history could reveal an unsuspected history of traumatic delivery or neonatal intubation.

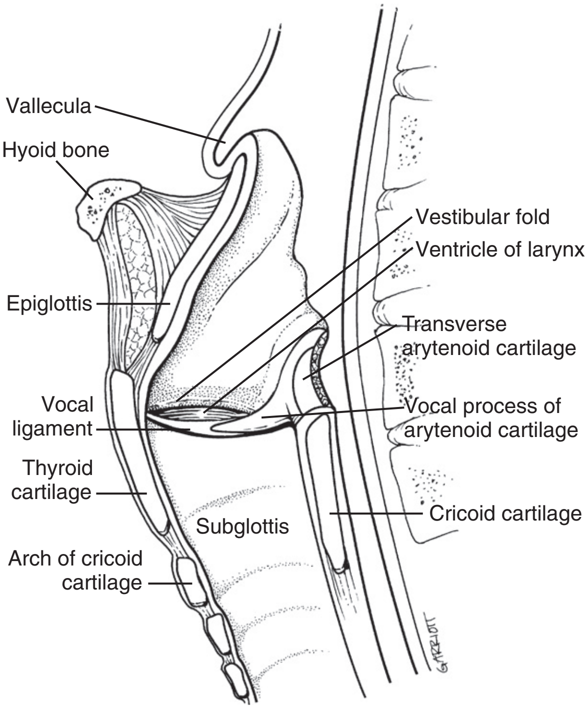

Figure 44–70. Parasagittal view of infant larynx demonstrating cartilaginous relationships.

If the infant is in extremis or there are signs to suggest significant airway compromise, extreme caution should be exercised. Manipulation of the infant should be minimized until the airway can be secured. The infant can be observed for tachypnea, tachycardia, retractions (supraclavicular, subcostal, intercostal), nasal flaring, cyanosis, drooling, cough, and level of consciousness (restless, agitated, stuporous) without increasing the level of the infant’s anxiety.

Laryngeal examination should not be performed in the infant with an unstable airway unless the appropriate personnel and equipment are available for urgent airway access when necessary. Flexible fiberoptic nasolaryngoscopy is widely available and allows direct inspection of the larynx in the stable neonate.

Evaluation of the awake child has several distinct advantages. The larynx can be viewed in a dynamic fashion so that the degree of laryngeal collapse during active respiration is appreciated. In addition, vocal cord motion can be assessed. Flexible bronchoscopy allows further dynamic evaluation of the subglottic airway and lower tracheobronchial tree.

For more controlled laryngeal evaluation, direct laryngoscopy and rigid bronchoscopy under general anesthesia are necessary. If a deep inhalational anesthetic technique is used, dynamic laryngeal and tracheal function can be assessed using this method as well. Direct laryngoscopy with rigid bronchoscopy is the method of choice in evaluating an infant with air hunger, cyanosis, or any critical symptoms that may necessitate intubation.

Ancillary testing in the infant with a stable airway is useful in further identifying the site of the lesion before possible endoscopy and surgical intervention. Radiographic evaluation of the upper airway (usually with a CT scan with contrast) is useful in suspected subglottic stenosis (either congenital or iatrogenic), soft tissue laryngeal tumors (hemangiomas, papillomas), or congenital laryngeal or esophageal cysts. Less commonly, anteroposterior and lateral soft tissue radiographs of the neck can be obtained. Ballooning of the hypopharynx is often seen on the lateral neck radiograph in an infant with significant airway obstruction. Reversal of the cervical lordotic curvature is suggestive of a retropharyngeal process. Airway fluoroscopy allows a dynamic assessment of the airway and can be done in conjunction with a modified barium swallow to evaluate for vascular anomalies or tracheoesophageal fistula or to better define the contribution of a swallowing disorder to the airway symptoms. CT scan is also useful for evaluating the infant with a laryngeal tumor, for a severe laryngotracheal anomaly not fully delineated by endoscopy, or for the evaluation of laryngeal trauma. CT scanning is also useful for virtual bronchoscopy to map extensive tracheal or bronchial stenosis. MRI is useful for defining mediastinal anatomy in the infant with a suspected vascular anomaly.

Disorders of the neonatal larynx are best subdivided into congenital and acquired lesions. Severe congenital laryngeal anomalies are quite rare and in general manifest themselves within the first few minutes of life. These include complete atresia, severe stenosis, or near-total laryngeal webs. If these disorders are recognized, tracheostomy may be a life-saving procedure. Often these severe laryngeal anomalies are found in conjunction with other life-threatening neurologic, cardiac, gastrointestinal, and lower airway lesions. In the neonate, the acquired laryngeal injury is usually the result of endotracheal intubation (see Part 4). The overall prognosis for these neonates depends not only on the laryngeal problem but also on the infant's overall development and the impact of other concomitant lesions.

Laryngomalacia

Laryngomalacia (congenital flaccid larynx, congenital laryngeal stridor) is the most common cause of stridor in the infant and accounts for up to 60% of laryngeal problems in the pediatric population.[15] Clinically, the stridor develops between the second and fourth weeks of life, although it occasionally may be present at birth. The stridor is typically characterized as coarse inspiratory noise.

The infant is generally better in the prone position, because this serves to decrease the degree of supraglottic collapse on inspiration. Agitation tends to exacerbate the stridor, and stridor tends to disappear completely during rest. Feeding difficulties are unusual and cry is normal. However, the infant may present with failure to thrive. In these cases, surgical intervention is necessary. Severe airway obstruction is unusual and is generally seen in infants with underlying neuromuscular disorders.

The natural history of the disease is one of progression until 8 to 12 months of age, with complete resolution in most children by 2 years of age. The etiology of laryngomalacia remains elusive, although generalized neurologic immaturity of the infant's airway and digestive tract is believed to play a role. Gastroesophageal reflux is often present in these children and can affect the severity of the laryngeal symptoms.[20]

When the stridor is not associated with any severe cyanotic spells, fiberoptic office nasolaryngoscopy is useful in confirming the diagnosis of laryngomalacia. During inspiration, the supraglottic structures collapse into the laryngeal inlet, narrowing the air passage and creating the classic coarse stridor. Collapse of the arytenoids is often a key component in the development of clinically significant obstruction, rather than isolated epiglottic prolapse as initially hypothesized.

Airway fluoroscopy and modified barium swallow are useful adjuvants in the evaluation of these infants. Often, the skilled airway fluoroscopist can support the diagnosis of laryngomalacia. The subglottic airway may be indirectly evaluated using this technique, and a search can be made for possible vascular anomalies affecting the integrity of the airway.

Up to 20% of infants with laryngomalacia have a second airway lesion, most commonly congenital subglottic stenosis.[2] Direct laryngoscopy with rigid bronchoscopy is indicated in the atypical patient to confirm the suspected diagnosis of laryngomalacia and to evaluate for the possible existence of a secondary lesion below the level of the glottis.

In most cases, therapy for laryngomalacia is observation and reassurance. In more severe cases with feeding difficulties, endoscopic laser aryepiglottic fold incision (epiglottoplasty) can provide symptomatic relief without the need for tracheostomy (Fig. 44-71).[24,26] Tracheostomy is reserved for severe laryngomalacia that results in significant airway obstruction despite epiglottoplasty.

Bifid or Absent Epiglottis

Both the bifid epiglottis and the absent epiglottis are extremely rare (Fig. 44-72). Severe subglottic stenosis is usually seen with these unusual supraglottic anomalies. Tracheostomy is necessary because of the associated subglottic lesion. Aspiration is variable.

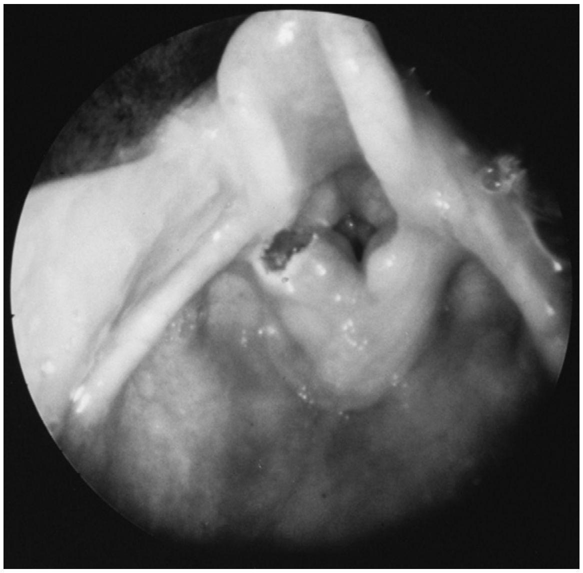

Figure 44–71. Infant supraglottis. Laser epiglottoplasty for laryngomalacia has been performed by cutting the left aryepiglottic fold.

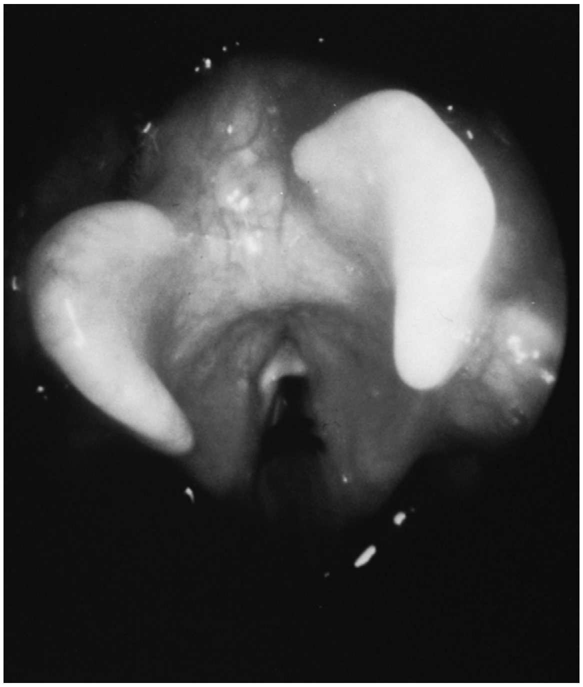

Figure 44–72. Bifid epiglottis.

Laryngeal Cysts

Most cysts of the larynx develop in the supraglottic location (aryepiglottic fold, epiglottis, vallecula) and gradually increase in size during the first few months of life (Fig. 44-73). Owing to the location of these lesions as well as their slowly progressive course, they may be indistinguishable clinically from laryngomalacia. These patients often have inspiratory stridor that worsens with agitation and when in the supine position. In older children, the voice can become muffled as the cyst enlarges. Progressive dysphagia with aspiration is more commonly seen in these patients than in patients with classic laryngomalacia.[6]

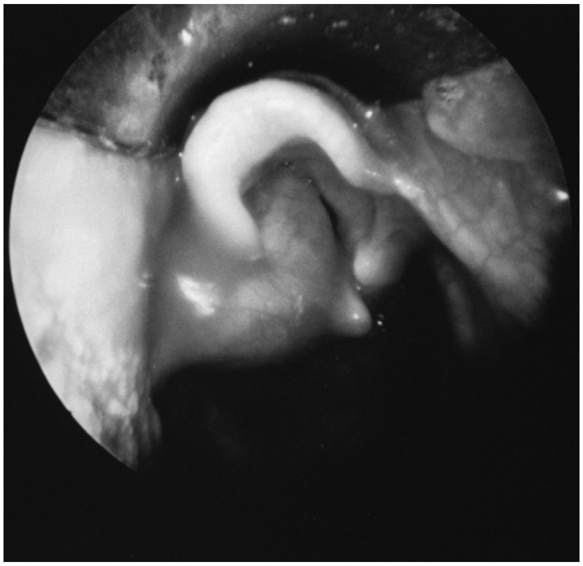

Figure 44–73. Infant supraglottis: left aryepiglottic fold cyst with glottic obstruction.

If undetected and untreated, these cysts can become quite large and cause complete laryngeal obstruction. Fiberoptic evaluation confirms the presence of a supraglottic cyst and is the minimum requirement for all infants with new-onset, progressive inspiratory stridor. The treatment involves either endoscopic marsupialization or complete excision (either endoscopically or externally) of the cyst. Attempts to aspirate the cyst inevitably lead to cyst recurrence. Subglottic cysts can form just below the vocal cords and are caused by obstruction of mucosal glands related to intubation. Endoscopic marsupialization with the carbon dioxide laser is usually curative.

Vocal Cord Paralysis

Vocal cord paralysis is second only to laryngomalacia as a cause of stridor in the pediatric patient, accounting for 10% to 15% of new cases.[15] Although the paralysis might not be a true congenital lesion, it is often present at birth and is therefore grouped with other congenital anomalies of the larynx. Most of these lesions are unilateral.

Clinically, the infant is often symptomatic within the first week of life. In the case of unilateral injury, the infant might have a weak cry but develops stridor only when stressed (agitation, infection). The stridor is typically either inspiratory or biphasic in character. The child may have a history of choking, coughing, or brief cyanotic spells during feeds, which is indicative of aspiration.

Radiographic evaluation remains an important step in the management of these patients. Unilateral paralysis may be associated with cardiac atrial enlargement or anomalous great vessels, which can be detected on chest radiographs and barium swallow or echocardiogram. In the absence of a history of traumatic delivery or cardiothoracic surgery (e.g., ligation of patent ductus arteriosus [PDA], repair of tracheoesophageal fistula) that might have resulted in injury to the vagus or recurrent laryngeal nerve, the course of the vagus nerve should be investigated radiographically with a CT scan. Fiberoptic evaluation to confirm the diagnosis of vocal cord paralysis may be difficult if significant laryngomalacia is present, obscuring visualization of the laryngeal inlet during vocalization (crying). Ultrasonographic imaging is an alternative technique for assessing vocal cord function in the difficult patient.[10]

The treatment of unilateral vocal cord paralysis depends on the severity of the child's symptoms. Often the respiratory symptoms are minimal, and adjustments in the infant's diet could eliminate the problem with aspiration. Most cases of unilateral paralysis resolve spontaneously over 6 to 12 months. Direct surgical management of the paralyzed vocal cord is therefore generally not recommended. Tracheostomy is rarely necessary in unilateral vocal cord paralysis.

Bilateral paralysis creates more severe respiratory symptoms due to significant encroachment on the glottic aperture. Often, there are associated neurologic abnormalities, such as Chiari malformation and hydrocephalus, in infants with bilateral vocal cord paralysis. Evaluation of the infant with bilateral vocal cord paralysis should therefore include CT or

MRI imaging of the central nervous system and the base of the skull. Unlike unilateral paralysis, bilateral vocal cord paralysis often necessitates tracheostomy.

Laryngeal Web

A laryngeal web is the result of a failure to recanalize the laryngeal inlet at approximately 10 weeks' gestation. The web is a membrane of varying thickness and most frequently involves the glottis from the anterior commissure to the vocal process (Fig. 44-74). The infant might not be symptomatic at birth. As the level of activity increases, usually between 4 and 6 weeks of age, the infant develops biphasic stridor. The cry is often weak, and in severe cases the infant may be nearly aphonic. Feeding is not affected. Treatment of a laryngeal web depends on the thickness of the web itself and the degree of subglottic extension. Thin webs can often be treated endoscopically with the carbon dioxide laser. Thicker, more fibrotic webs might require tracheostomy and an external approach with stent or keel placement.

Congenital Subglottic Stenosis

The normal subglottis measures between 5 and 7 mm in the neonate. Congenital subglottic stenosis occurs when the subglottic diameter of a full-term infant is less than 4 mm at birth. Congenital stenosis often results from an abnormally shaped cricoid ring, elliptical rather than circular, or from excessive thickening of the subglottic tissue. Rarely, the first tracheal ring may be displaced superiorly and come to lie within the cricoid itself.

In mild forms, the stenosis can go undetected until the child is 2 to 3 years of age, at which point recurrent crouplike episodes prompt endoscopic evaluation. In more severe cases, biphasic stridor is present with a classic croupy cough in the absence of any systemic signs of a viral illness. The cry is usually normal, and feeding is only an issue in cases of significant shortness of breath due to airway compromise. In general, congenital subglottic stenosis is concentric. Radiographic evaluation usually demonstrates symmetric subglottic narrowing.

Management of these lesions depends on the severity of the infant's symptoms and the age at presentation. Congenital subglottic stenosis is usually less severe than the iatrogenic form following endotracheal intubation. In select cases, an anterior cricoid split can prevent the need for tracheostomy in infants up to 18 months of age. In more severe cases of stenosis or in the older child, laryngotracheal reconstruction using rib for augmentation is the treatment of choice.

Subglottic Hemangioma

Subglottic hemangioma is the most common neoplasm of the infant airway and can lead to significant airway compromise if left untreated. A hemangioma is a vascular neoplasm characterized by proliferation of the capillary endothelium.[32] In the larynx, the lesion generally appears as a smooth, eccentric, compressible mass in the subglottis, most commonly located in the left, posterior subglottic space. Up to 50% of infants with a documented subglottic hemangioma have a cutaneous lesion as well.

The clinical presentation of a subglottic hemangioma is similar to that of subglottic stenosis. The infant typically has progressive biphasic stridor beginning at 4 to 6 weeks of age. Unlike with the static subglottic lesion, the symptoms associated with a hemangioma can fluctuate in severity from day to day. The fluctuating character of symptoms is strongly diagnostic of subglottic hemangioma. The stridor is worse with crying or agitation owing to vascular engorgement of the hemangioma. Feeding difficulties are unusual unless severe airway obstruction exists. The cry is generally normal. Radiographic evaluation (CT scan with contrast or anteroposterior soft tissue neck film) may show an asymmetric narrowing of the subglottis. The diagnosis of a subglottic hemangioma is confirmed at the time of direct laryngoscopy with rigid bronchoscopy (Fig. 44-75).

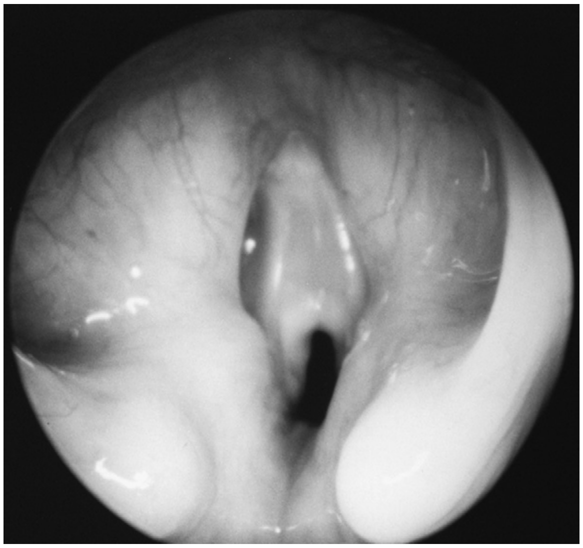

Figure 44–74. Glottic web.

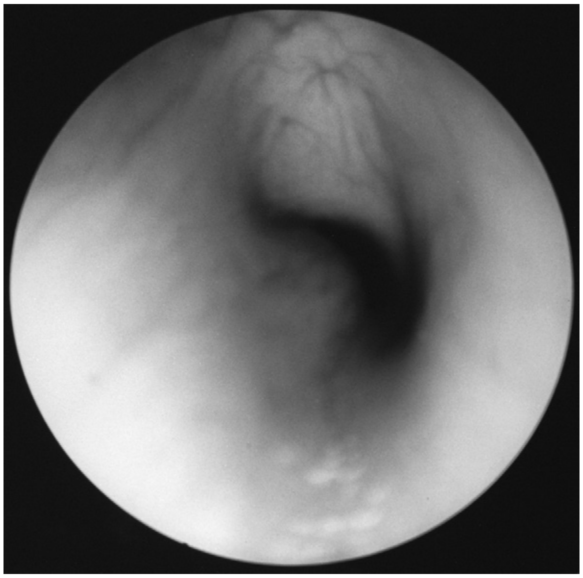

Figure 44–75. Subglottic hemangioma before treatment.

The treatment of subglottic hemangiomas must take into account the natural history of the neoplasm. Initially, the lesion undergoes rapid postnatal growth for 8 to 18 months (proliferative phase) followed by slow but inevitable regression for the next 5 to 8 years (involutive phase). Systemic steroids on a daily or every-other-day schedule may control the proliferative phase of the hemangioma in patients with minimal airway or feeding compromise and obviate the need for further surgical intervention. The CO_2 laser is a valuable tool in the treatment of larger lesions and those less responsive to systemic steroid therapy.[29] In cases of extensive airway involvement, a tracheostomy provides a secure airway until the tumor involutes. In patients with life-threatening or function-threatening hemangiomas who have failed or don't tolerate corticosteroid or other conservative management, other pharmacologic therapies (e.g., interferon, vincristine, or propanolol) may be considered.[21,25,27]

Laryngeal Cleft

Failure of fusion of the posterior cricoid lamina results in a posterior laryngeal cleft. This rare developmental anomaly usually manifests with respiratory distress precipitated by feeding. Other congenital anomalies are known to be associated with this lesion. If the cleft is mild, often dietary changes (thickened feeds) are sufficient to prevent aspiration. A gastrostomy is recommended if thickened feeds do not prevent aspiration, and open repair is advocated.

Congenital High Airway Obstruction Syndrome

Congenital high airway obstruction syndrome (CHAOS) was defined by Hedrick and colleaguesl[13] in 1994 as prenatally-diagnosed upper airway obstruction with concomitant findings of large echogenic lungs, dilated airways, flattened or inverted diaphragms with associated fetal ascites, or nonimmune hydrops. These hallmark findings are found consistently only when there is complete high upper airway obstruction with no tracheoesophageal connection. This leads to trapping of the fluid secreted by the fetal lung tissue. If the lung fields expand to the point of producing esophageal compression, then polyhydramnios may occur as a result of impaired swallowing of amniotic fluid. These findings necessitate a more detailed scan for other abnormalities because CHAOS may be one fetal presentation of Fraser syndrome characterized by variable expression of laryngeal atresia, cryptophthalmos, syndactyly, renal agenesis, and abnormalities of the ears and external genitalia.[22]

Possible airway anomalies include complete laryngeal atresia, severe congenital subglottic stenosis, and significant laryngeal web.[12] A laryngeal cyst that completely occludes the airway is less common.

This life-threatening condition was previously thought to be rare and uniformly fatal. Advances in prenatal imaging techniques have enabled this syndrome to be recognized more readily. Planning for the EXIT (ex utero intrapartum treatment) procedure can then be made to maximize survival.

If there is incomplete airway obstruction or a tracheoesophageal fistula, then the degree of fluid trapping is lessened and the diagnosis is less obvious on prenatal ultrasound imaging. In these cases, with the diagnosis less obvious, survival depends on the degree of upper airway obstruction, the ability to tracheally intubate the child past the tracheoesophageal fistula or the ability to expeditiously perform a tracheostomy.

Intubation Trauma

The use of endotracheal intubation to secure the airway in the neonate for mechanical ventilation has become the standard of care for the critically ill newborn. Despite recent efforts to reduce the risk of iatrogenic injury, however, granuloma formation, arytenoid dislocation with true vocal cord fixation, and subglottic stenosis continue to occur.

Granuloma formation can follow endotracheal intubation. The infant is often hoarse following extubation, with progression rather than improvement of the symptoms with time. Evaluation of the larynx reveals a yellow-red pedunculated mass arising from the vocal process of the arytenoid. Subglottic cysts or mucoceles may develop when the opening of submucosal glands is interrupted by tissue reaction from an endotracheal tube. Microlaryngoscopy and removal of these lesions often result in resolution of the infant's symptoms. Repeat evaluation is recommended at 2 to 3 weeks to ensure that the granuloma has not reformed, which can be lessened by aggressive treatment of gastroesophageal reflux.

Several factors in the pediatric airway predispose the intubated neonate to subglottic stenosis (Fig. 44-76). The subglottic lumen is the narrowest aspect of the pediatric larynx. Premature infants and children with Down syndrome tend to have smaller cricoid rings than normal, thus increasing the overall risk of subglottic stenosis. Gastroesophageal reflux is an important factor in the pathogenesis of subglottic stenosis and is more frequently encountered in the premature infant and young child.[23] Difficulty in stabilizing the endotracheal tube in the neonate often results in repeated intubations and increased injury to the subglottis. Extreme immaturity

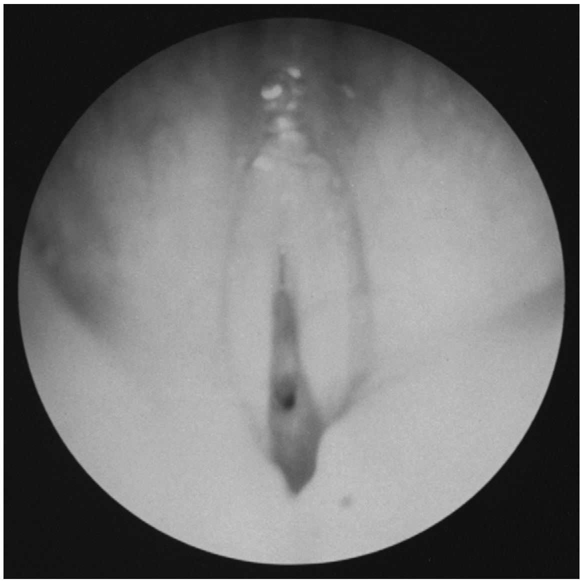

Figure 44–76. Iatrogenic subglottic stenosis following prolonged endotracheal intubation in a neonate.

requiring intubation periods of several months predisposes to subglottic injury. Hypoxia and sepsis are important variables in the development of subglottic tissue damage and are commonly seen in the neonatal intensive care setting. Injury to the subglottis may be reduced if the following steps are taken:

- Use smaller endotracheal tubes.
- Avoid cuffed endotracheal tubes in the infant and young child.
- Aggressively treat systemic infection.
- Minimize patient movement to prevent abrasions of the subglottic mucosa and resultant exposed cartilage as well as to prevent accidental extubation requiring further manipulation (sedation as necessary).
- Consider tracheostomy if prolonged intubation is anticipated. Neonates tolerate intubation for much longer periods than the child or young adult.
- Extubate under ideal conditions. In the difficult airway, high-dose systemic steroids for 24 to 48 hours before and after extubation may aid extubation. Use of inhaled epinephrine immediately following extubation can help reduce airway edema.

Treatment of iatrogenic subglottic stenosis depends on the severity of the stenosis, the age of the child, and concomitant medical problems. Tracheostomy remains the cornerstone of treatment, especially in the infant with multilevel airway involvement, multisystem failure, or significant pulmonary disease. The anterior cricoid split may be used in the neonate up to 18 months of age if mild stenosis exists. As in congenital subglottic stenosis, laryngotracheal reconstruction using rib cartilage is the method most commonly employed for treatment of significant pediatric subglottic stenosis. In selected patients, laryngotracheal reconstruction may be performed as a single-stage procedure, allowing immediate decannulation in the patient with a preexisting tracheostomy or avoidance of a tracheostomy altogether in the virgin trachea.

SUMMARY

Management of the neonate with upper airway obstruction requires that a rapid evaluation and diagnosis be made based on a complete understanding of the unique anatomic and physiologic characteristics of the neonatal airway. The airway should be assessed from nasal vestibule to tracheal bifurcation in a search for the etiology of acute or progressive respiratory distress. Treatment of the neonate with upper airway pathology is tailored to the specific abnormality as well as coexisting medical problems.

PART 7

Bronchopulmonary Dysplasia

Eduardo H. Bancalari and Michele C. Walsh

The introduction of mechanical ventilation for the management of premature infants with severe respiratory distress syndrome (RDS) in the 1960s changed the natural course of the disease, resulting in increased survival of smaller and sicker infants, many of whom had severe chronic lung damage. Northway and associates were the first to describe this condition in 1967 and introduced the term *bronchopulmonary dysplasia* (BPD).[43]

All infants in this original description were born prematurely, had severe respiratory failure, and received prolonged mechanical ventilation with high airway pressures and fraction of inspired oxygen (FiO_2). Their clinical and radiographic course ended with severe chronic lung changes characterized by persistent respiratory failure with hypoxemia and hypercapnia, frequent cor pulmonale, and a chest radiograph that revealed areas of increased density due to fibrosis and collapse surrounded by areas of marked hyperinflation.

Currently, this severe form of chronic lung disease (CLD) is less common and has been replaced by a milder form of chronic lung damage that occurs in many very small preterm infants who, with increasing frequency, are surviving after prolonged periods of mechanical ventilation. This milder form of lung damage often occurs in infants who initially have only mild pulmonary disease and do not require high airway pressures or FiO_2.[35,49] The terms *BPD* and *CLD* have been used interchangeably but because the term *BPD* is more specific to the neonatal lung disease, this term is preferred here.

The incidence of BPD varies widely among different centers.[4] This is not only due to differences in patient susceptibility and in management but also to discrepancies in the way BPD is defined.[8] In 2001, a workshop conducted by the National Institutes of Health (NIH) proposed a definition that divides BPD into three categories based on the duration and level of oxygen therapy required (Table 44-7). Ehrenkranz and colleagues explored the validity of the NIH Consensus definition in the large NICHD Neonatal Research Network database.[24] Use of the consensus definition increases the number of infants diagnosed with BPD by adding the group who were on oxygen at 28 days of age, but in room air at 36 weeks to those defined as having BPD. The overall rate of BPD was increased from 46% to 77%. The assessment of severity of BPD adds richness to the outcome measure and identifies a spectrum of adverse pulmonary and neurodevelopmental outcomes. As the severity of BPD increases, the incidence of adverse events also increases. Also, the criteria for administering supplemental oxygen can greatly affect the reported incidence of BPD. A physiologic test to standardize the need for supplemental oxygen has been proposed as a way of reducing the variability in diagnostic criteria.[63]

With increasing survival of very small premature infants, the number of patients at risk of developing BPD increases. Available data suggest that surfactant therapy for RDS decreases mortality without independently affecting the incidence of BPD, but when both endpoints are combined the number of survivors without BPD is increased.[52]

The incidence of BPD in infants with RDS who receive intermittent positive-pressure ventilation (IPPV) is inversely related to the gestational age and birthweight, and although it can occur in full-term infants, it is uncommon in infants born after 32 weeks of gestation. Figure 44-77 shows the incidence of BPD in infants born in the United States between 1997 and 2002 and published in 2007.[25]

CLINICAL PRESENTATION

The diagnosis of BPD is based on the clinical and radiographic manifestations, but these are not specific. With rare exceptions, BPD follows the use of mechanical ventilation with IPPV during the first weeks of life. Mechanical ventilation is usually indicated for respiratory failure resulting from RDS, pneumonia, or poor respiratory effort. The development of BPD is often anticipated when mechanical ventilation and oxygen dependence extend beyond 10 to 14 days.

The major radiographic features of the more severe forms of BPD include hyperinflation and nonhomogeneity of pulmonary fields, with multiple fine or coarser densities extending to the periphery (Fig. 44-78). Only a radiographic picture showing chronic pulmonary involvement plus a clinical course that is compatible with BPD justifies this diagnosis with some degree of consistency. Once lung damage has occurred, these infants require mechanical ventilation and increased FiO_2 for several weeks or months.

Presently, most of these small infants have mild respiratory disease initially requiring ventilation with low pressures and oxygen concentration, but after a few days or weeks of

TABLE 44–7 Definition of Bronchopulmonary Dysplasia: Diagnostic Criteria

Gestational Age	<32 Weeks	≥32 Weeks
Time point of assessment	36 weeks' PMA or discharge to home, whichever comes first	>28 days but < 56 days' postnatal age or discharge to home, whichever comes first
	Treatment with > 21% Oxygen for at least 28 Days PLUS	
Mild BPD	Breathing room air 36 wk PMA or discharge, whichever comes first	Breathing room air by 56 days' postnatal age or discharge, whichever comes first
Moderate BPD	Need for < 30% oxygen at 36 wk PMA or discharge, whichever comes first	Need for < 30% oxygen at 56 days' postnatal age or discharge, whichever comes first
Severe BPD	Need for ≥ 30% oxygen and/or positive pressure (PPV or NCPAP) at 36 wk PMA or discharge, whichever comes first	Need for ≥ 30% oxygen and/or positive pressure (PPV or NCPAP) at 56 days' postnatal age or discharge, whichever comes first

BPD, bronchopulmonary dysplasia; NCPAP, nasal continuous positive airway pressure; PMA, postmenstrual age; PPV, positive pressure ventilation.

mechanical ventilation they show progressive deterioration in their lung function and BPD develops. This deterioration is often triggered by pulmonary or systemic infections or increased pulmonary bloodflow secondary to a patent ductus arteriosus (PDA).[27] In these cases the functional and radiographic changes are usually milder, revealing more diffuse haziness without the marked changes observed in the severe forms of BPD (Fig. 44-79). This entity has been termed *atypical BPD* or *new BPD.*[15,35]

Most survivors show a slow but steady improvement in their lung function and radiographic changes and, after variable periods, can be weaned from respiratory support and supplemental oxygen, but most infants persist with signs of respiratory compromise. In many infants, lobar or segmental atelectasis develops, resulting from retained secretions and airway obstruction.

Infants with more severe lung damage could die of progressive respiratory failure, cor pulmonale, or acute complications, especially intercurrent infections. In these infants, severe airway damage with bronchomalacia can lead to severe airway obstruction, especially during episodes of agitation and increased intrathoracic pressure.[40] Furthermore, anastomoses

between the systemic and pulmonary circulations can aggravate their pulmonary hypertension.

Because of the respiratory failure, infants with BPD take oral feedings with difficulty and often require nasogastric or orogastric feeding. Weight gain is usually less than the expected normal even when they receive an amount of calories appropriate for their age. This lower weight gain can be due to chronic hypoxia and to the higher energy expenditure required by the increased work of breathing in these infants.

Signs of right heart failure may develop secondary to pulmonary hypertension, with cardiomegaly, hepatomegaly, and fluid retention. In these cases, the need for fluid restriction further limits the number of calories that can be provided. Right ventricular heart failure is seen less commonly than in the past, most likely because milder forms of BPD are seen today and because of the more aggressive maintenance of normal levels of oxygenation.

The diagnosis of BPD is based on the clinical and radiographic course described earlier, but these signs are not specific for any given etiology. For this reason, specific etiologies that could lead or contribute to the lung damage must be considered before concluding that the infant has BPD. Among these, one must rule out congenital heart disease, pulmonary lymphangiectasia, chemical pneumonitis resulting from recurrent aspiration, cystic fibrosis, or disorders of surfactant homeostasis.

PATHOLOGY

Macroscopically, the lungs of infants with severe BPD have a grossly abnormal appearance. They are firm and heavy and have a darker color than normal. The surface is irregular, often showing emphysematous areas alternating with areas of collapse (Fig. 44-80). On histologic examination the lungs are characterized by areas of emphysema, sometimes coalescing into larger cystic areas, surrounded by areas of atelectasis (Fig. 44-81). Widespread bronchial and bronchiolar mucosal hyperplasia and metaplasia reduce the lumina in many of the small airways and can interfere with mucus transport (Fig. 44-82).

In some cases, excessive mucus persists throughout the course of the disease, but the involvement of the small airways is more prominent during the early stages, becoming less marked after the first months of evolution. In addition, there is interstitial edema and an increase in fibrous tissue with focal thickening of the basal membrane separating capillaries from alveolar spaces (Fig. 44-83). Lymphatics are usually dilated

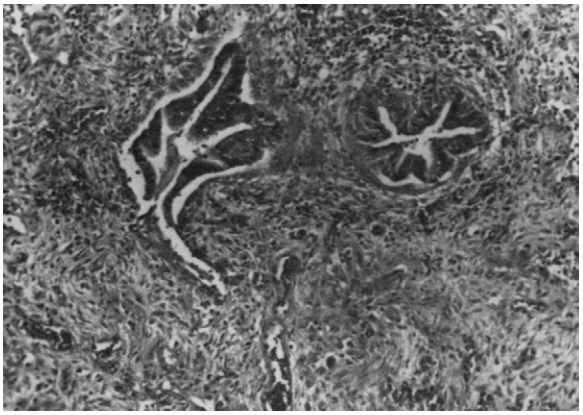

Figure 44–82. Small airways showing hyperplasia of the epithelium partially obstructing the lumen. Peribronchial muscle is hypertrophied, most alveoli are collapsed, and there is an increase in interstitial fibrous tissue. *(From Bancalari E, et al: Barotrauma to the lung. and tortuous. Often there are vascular changes of pulmonary hypertension, such as medial muscle hypertrophy and elastic degeneration, and there is a reduction in the branching of the pulmonary vascular bed. There also may be evidence of right ventricular hypertrophy and, in many cases, left ventricular hypertrophy as well.

Infants who receive antenatal steroids and surfactant and have milder forms of BPD have a more diffuse injury with less emphysema and little or no fibrosis. A striking morphologic change in lungs with BPD is a marked reduction in the number of alveoli and capillaries and a reduction in the gas exchange surface area.[16,33,35] It is not known whether this alteration is reversible with increasing age, but it is the most striking and consistent change in the lungs of infants who die with BPD today.

PATHOGENESIS

BPD occurs almost exclusively in preterm infants who receive mechanical ventilation with positive pressure; therefore prematurity and mechanical overdistention have been considered the most important factors in the pathogenesis of BPD. Other factors that can contribute to the pathogenesis of BPD are oxygen toxicity, pulmonary or systemic infections, pulmonary vascular damage, and edema resulting from a PDA or excessive fluid administration.

Prematurity

The prevalence of BPD in mechanically ventilated infants is inversely related to gestational age and birthweight, strongly suggesting that incomplete development of the lungs plays an important role in the pathogenesis of BPD. As mentioned earlier, BPD is extremely uncommon in infants older than 32 to 34 weeks of gestation.

Mechanical Trauma

Although some forms of chronic lung damage have been described in infants who were not ventilated, most premature infants with BPD have received mechanical ventilation, although this may not be prolonged. This, plus the frequent association between pulmonary interstitial emphysema (PIE) and BPD, has led to the conclusion that lung overdistention secondary to positive pressure ventilation plays an important role in the pathogenesis of BPD. In fact, the lower incidence of BPD at some centers could be largely attributable to avoidance of mechanical ventilation in extremely premature infants.[58] The role of the endotracheal tube itself is difficult to separate from that of the mechanical ventilation, but the tube hinders the drainage of bronchial secretions and increases the risk of pulmonary infections.

Although peak inspiratory pressure is a major factor implicated as a cause of BPD, it is difficult to determine whether the high pressures have a causal effect on the chronic lung damage or whether these high settings are required after lung damage is already established. The damaging effect of high airway pressure and tidal volume on the surfactant-deficient lung has been demonstrated in preterm experimental animals. Lung compliance was decreased after only a few breaths with excessive tidal volumes given before surfactant replacement.[11] No significant differences in the incidence of BPD have been shown between infants ventilated with low pressures and prolonged inspiration and those ventilated with higher pressures and shorter inspiration, but experimental evidence strongly suggests that excessive tidal volumes can damage the lung, initiate an inflammatory cascade, and interfere with normal lung development. (See Part 4.)

Finally, the duration of assisted ventilation and duration of oxygen therapy could be important factors in the pathogenesis of BPD, but it is difficult to separate their role from the severity of the underlying disease. The smaller the infant and the more severe the disease, the higher the settings and the longer the time required for assisted ventilation.

Oxygen Toxicity

Clinical and experimental evidence suggest that pulmonary oxygen toxicity is a major factor in the pathogenesis of BPD. Although many tissues can be injured by high oxygen concentrations, the lung is exposed directly to the highest partial pressure of oxygen. The precise concentration of oxygen that is toxic to the immature lung probably depends on a large number of variables, including gestational age, nutritional and endocrine status, and duration of exposure to oxygen and other oxidants. Although a safe level of inspired oxygen has not been established, any concentration in excess of room air might increase the risk of lung damage when administered over a period of many days.

The pulmonary changes of oxygen toxicity are nonspecific and consist of atelectasis, edema, alveolar hemorrhage, inflammation, fibrin deposition, and thickening of alveolar membranes. There is early damage to capillary endothelium in animals, and plasma leaks into interstitial and alveolar spaces. Pulmonary surfactant can be inactivated, adding to the risk of atelectasis. Type I alveolar lining cells also are injured early, and bronchiolar and tracheal ciliated cells can also be damaged by oxygen. Total resolution after oxygen toxicity is possible if the initial exposure is not overwhelming. Cellular pathologic processes similar to those described in animals probably also occur in humans.

Continued exposure to high inspired oxygen levels is accompanied by influx of polymorphonuclear leukocytes containing proteolytic enzymes. In addition, the antiprotease defense system is significantly impaired in infants exposed to prolonged high inspired oxygen levels, favoring proteolytic damage of structural elements in alveolar walls. This could be an important pathogenic factor in oxygen toxicity and BPD. High inspired oxygen has also been shown to interfere with the process of alveolar and capillary formation.

Although the cellular basis for oxygen toxicity has not been completely elucidated, the principal mechanisms involve the univalent reduction of molecular oxygen and formation of free radical intermediates. The latter can react with intracellular constituents and membrane lipids, thus initiating chain reactions that can cause tissue destruction (Fig. 44-84).

To resist the detrimental effects of oxygen, the organism has evolved a number of antioxidant systems. Antioxidant enzymes such as superoxide dismutase, catalase, and glutathione peroxidase seem to play an important role in preventing the toxic effects of oxygen. Other elements, such as vitamin E, glutathione, and selenium are also part of the endogenous antioxidant mechanisms. The capacity for synthesizing these enzymes in some animal species follows a maturational trend similar to the production of surfactant; therefore animals born prematurely have lower concentrations of antioxidant enzymes than those born at full term.

Loss of mucociliary function may be an additional pathogenic factor in BPD because exposure to high oxygen concentrations results in a reduction of ciliary movements.

Infection and Inflammatory Reaction

Increasing evidence supports the role of antenatal and postnatal infections in the development of BPD. The role of infection appears to be especially important in very small infants in whom the occurrence of nosocomial infections is associated with a marked increase in the risk for development of BPD.[49] This is even more striking when the infection occurs in an infant with a PDA.[27] Evidence suggests that perinatal adenovirus and cytomegalovirus infection might also increase the risk for BPD.

Several studies have suggested an association between *Ureaplasma urealyticum* tracheal colonization and the development of severe respiratory failure and BPD in infants with very low birthweight, but results have not been consistent.[17,31,44,64] There is also increasing evidence that maternal infections and specifically chorioamnionitis are associated with an increased risk of BPD in the infant.[65,71]

The role of inflammatory reaction in the development of BPD is receiving more attention. Inflammation could be triggered by factors such as oxygen, positive pressure ventilation, PDA, and prenatal or postnatal infections. Increased concentration of inflammatory mediators could contribute to the bronchoconstriction and vasoconstriction and the increased vascular permeability characteristic of these infants.[28] The inflammatory reaction might also be responsible for the decreased alveolarization characteristic of infants with BPD.[13,35,68]

Bronchoalveolar fluid examinations in infants with BPD reveal elevated neutrophil counts and increased elastase.[67] Increased desmosine excretion in the urine during the first week of life has been described in infants who subsequently develop BPD, indicating increased elastin degradation resulting from lung inflammation and injury. On the other hand, higher concentrations of fibronectin have been measured in tracheal lavage fluid from infants with BPD, which could foster the development of interstitial fibrosis in these patients.

Inflammatory mediators such as chemokines, interleukin, leukotrienes, and platelet activating factor also are found in high concentrations in lung lavage fluid of infants with BPD.[5,9,28] The potential role of inflammation is supported by the reported beneficial effects of steroids and possibly cromolyn sodium in some infants with BPD.[20]

Pulmonary Edema and Patent Ductus Arteriosus

There is an association between the presence of a PDA and the increased risk for BPD (Fig. 44-85).[27,49] Clinical evidence suggests that infants with RDS who receive greater fluid intake or do not show a diuretic phase during the first days of life have a higher incidence of BPD.[57] This may be because high fluid intake increases the incidence of a PDA. Increased pulmonary bloodflow because of PDA and the resulting increase in interstitial fluid cause a decrease in pulmonary compliance.[26] Combined with increased airway resistance, this can prolong the need for mechanical ventilation with higher ventilatory pressures and oxygen concentrations, increasing the risk for BPD. Moreover, the increased pulmonary bloodflow can also induce neutrophil margination and activation in the lung and contribute to the progression of the inflammatory cascade.[60]

Recent data from studies in preterm baboons showed decreased alveolarization in animals that remained for a longer time with an open ductus arteriosus, supporting the role of a persistent ductus arteriosus in the pathogenesis of BPD.[41]

For unknown reasons, infants with BPD have a predisposition to fluid accumulation in their lungs. Possible causes are functional alterations in pulmonary vascular resistance, plasma oncotic pressure, and increased capillary permeability that favor the extravascular accumulation of fluid. Pulmonary vascular pressure can be increased because of hypoxemia, hypercapnia, and a reduced pulmonary vascular bed. In some cases, fluid accumulation it is secondary to the left ventricular dysfunction that has been described in patients with chronic respiratory failure. Plasma oncotic pressure is often decreased because of decreased plasma protein concentration resulting from poor nutrition. Capillary permeability might be increased secondary to the effects of high F_{IO_2}, mechanical trauma, increased flow due to a PDA, and infection on the capillary endothelium. During spontaneous breathing, the interstitial pressure in the lung is lower than normal because of the increased inspiratory effort necessary to overcome the low compliance and high pulmonary resistance. Finally, lymphatic drainage might be impaired because of compression of pulmonary lymphatics by interstitial fluid or gas and fibrous tissue, and because of the increased central venous pressure in cases of cor pulmonale.

Infants with BPD also have increased plasma levels of vasopressin and reduced urine output and free water clearance.[38] This is an additional alteration that can contribute to increased lung water in these patients. The abnormal accumulation of lung fluid in infants with BPD further compromises their lung function, perpetuating a cycle in which more aggressive respiratory assistance is required, which produces further lung damage.

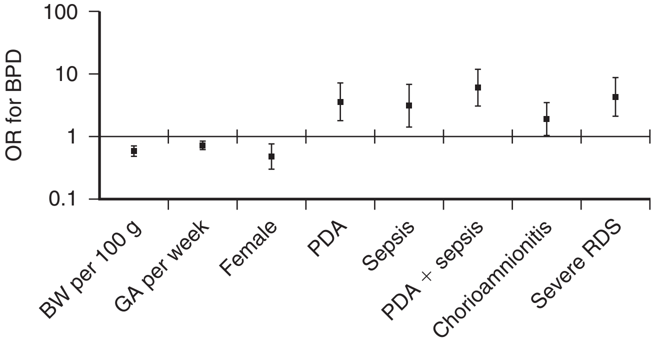

Figure 44–85. Perinatal and postnatal risk factors for bronchopulmonary dysplasia (BPD) defined as 28 days' duration of oxygen dependency during hospitalization. Obtained by logistic regression analysis from all extremely premature infants born at University of Miami Jackson Medical Center during the period 1995-2000. (*From* Bancalari E, *et al: Bronchopulmonary dysplasia: changes in pathogenesis, epidemiology and definition,* Semin Neonatol *8:63, 2003.)*

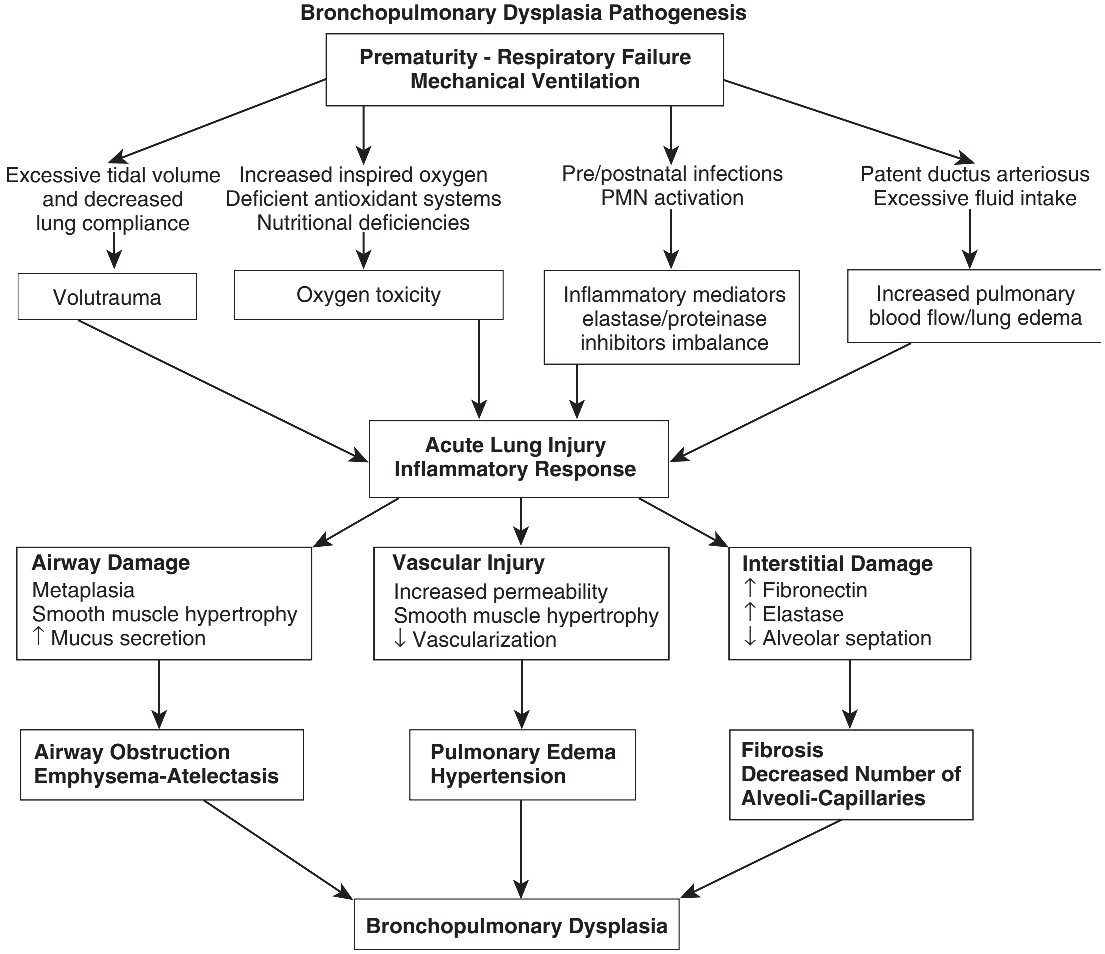
Airway Damage

Increased airway resistance can alter the time constant of different regions of the lung and impair the distribution of the inspired gas, favoring uneven lung expansion. Airway obstruction can occur in these infants secondary to the bronchiolar epithelial hyperplasia and metaplasia and to mucosal edema secondary to trauma, oxygen toxicity, and infection. Pulmonary edema secondary to PDA or fluid overload also can increase airway resistance. These infants could also have bronchoconstriction resulting from smooth muscle hypertrophy. Inflammatory mediators such as leukotrienes and platelet-activating factor are present in high concentrations in the airways of infants with BPD, possibly contributing to the increased airway resistance that is characteristic in these infants. In some infants with severe BPD, tracheobronchomalacia develops, which is responsible for marked airway obstruction, especially during periods of agitation and increased intrathoracic pressure.

Other Factors

A decreased concentration of α_1-proteinase inhibitor could be another factor that predisposes the neonatal lung to damage produced by elastase and other proteolytic enzymes derived from neutrophils. This is especially important when pulmonary infection supervenes.

The possibility of a genetic predisposition to abnormal airway reactivity in infants with BPD has also been raised because of a stronger family history of asthma in infants with BPD. There is also evidence that vitamin A deficiency could increase the risk for BPD in preterm infants. Infants with BPD had lower vitamin A levels than did those who recovered without lung sequelae. This possible association is supported by the similarities between some of the airway epithelial changes observed in BPD and vitamin A deficiency. Early adrenal insufficiency has also been suggested as a contributing factor in the development of BPD in the smallest infants. Infants with lower cortisol levels in the first week of life have an increased incidence of PDA, more lung inflammation, and increased incidence of BPD.[66]



Bronchopulmonary Dysplasia Pathogenesis

Figure 44–86. Algorithm for pathogenesis of bronchopulmonary dysplasia. PMN, polymorphonucleocytes.

Figure 44-86 summarizes some of the factors that have been implicated in the pathogenesis of BPD.

Prediction of Bronchopulmonary Dysplasia

A number of studies have been performed to develop scores that can predict the risk for BPD in ventilated preterm infants. Most of these scores include the state of maturation of the infant and factors that reflect the severity of the initial respiratory failure. These scores are helpful in identifying patients for clinical trials and could become more useful in the future if effective preventive therapies become available.

PULMONARY FUNCTION

The disruption of pulmonary function in BPD is explained by the severe structural alterations of these lungs. Minute ventilation is usually increased, but because of the lower lung compliance, this is accomplished with a smaller tidal volume and a higher respiratory rate than normal. Thus, there is an increase in dead space ventilation, partially accounting for the alveolar hypoventilation and CO_2 retention seen in these patients.

Infants with severe BPD characteristically have a marked increase in airway resistance and airway hyperreactivity.[48] This results in a decreased dynamic compliance, because with airway obstruction, dynamic compliance becomes frequency dependent; therefore, compliance decreases at higher respiratory rates. Lung compliance is also decreased because of fibrosis, overdistention, and collapse of lung parenchyma. It is also possible that some of these infants have a decreased concentration or inactivation of surfactant on their alveolar surface. The high resistance and decreased compliance result in a markedly increased work of breathing that contributes to the hypoventilation and hypercapnia.

Increased airway resistance is not specific for infants with BPD, and it is observed in many premature infants who survive after receiving IPPV, even when they do not have clinical or radiographic evidence of residual pulmonary disease. Airway resistance can be markedly increased, especially during active expiratory efforts associated with episodes of physical agitation. Airway obstruction can be severe in infants with tracheobronchomalacia.

Functional residual capacity is initially low or normal but could be increased later in cases of severe BPD. Infants with advanced BPD have abnormal distribution of ventilation, reflecting involvement of the small airways, but in infants with milder forms of BPD, the distribution of the inspired gas is usually normal as measured by nitrogen clearance delay.

Most infants with severe BPD have marked hypoxemia and hypercapnia and require supplemental oxygen to maintain acceptable oxygenation levels. The hypoxemia mainly results from a combination of ventilation-perfusion mismatch and alveolar hypoventilation. The oxygen requirement decreases gradually as the disease process improves, but it can increase during feedings, physical activity, or episodes of pulmonary infection or edema.

The increased $PaCO_2$ is also secondary to alveolar hypoventilation and to an increased alveolar-arterial CO_2 gradient produced by a ventilation-perfusion mismatch and increased alveolar dead space. The chronic hypercapnia often results in an increased serum bicarbonate concentration that tends to compensate for the respiratory acidosis. This increase in base is often exaggerated by the use of loop diuretics.

As discussed later, evaluation of pulmonary function in infants with BPD shows persistence of the abnormal airway function into adulthood in the more severe cases.

MANAGEMENT

Prevention of further lung damage is the cornerstone of management by avoiding, as much as possible, all factors that predispose to more injury.

Respiratory Support

See also Part 4.

When mechanical ventilation is used, the lowest peak airway pressure necessary to obtain adequate ventilation must be applied, using inspiratory times between 0.3 and 0.5 second. Shorter inspiratory times and higher flow rates can exaggerate the maldistribution of the inspired gas, but longer inspiratory times can increase the risk of alveolar rupture and cardiovascular side effects. An end-expiratory pressure between 4 and 6 cm H_2O is applied so that the minimum oxygen concentration necessary to keep the partial pressure of arterial oxygen (PaO_2) above 50 mm Hg is used. In infants with severe airway obstruction, especially those with bronchomalacia, the use of positive end-expiratory pressure levels of 5 to 8 cm H_2O can help reduce expiratory airway resistance and improve alveolar ventilation. The duration of mechanical ventilation must be limited as much as possible to reduce the risk of mechanical trauma and infection.

Weaning these patients from the ventilator is difficult and must be accomplished gradually. When the patient can maintain an acceptable PaO_2 and $PaCO_2$ with low peak pressures (lower than 15 to 18 cm H_2O) and an FiO_2 lower than 0.3 to 0.4, the ventilator rate is gradually reduced to allow the infant to perform an increasing proportion of the respiratory work. During the process of weaning, it may be necessary to increase the FiO_2. Concurrently, the $PaCO_2$ can rise, but as long as the pH is within acceptable limits, some degree of hypercapnia must be tolerated to wean the patient from the ventilator. In small infants, aminophylline or caffeine is used as a respiratory stimulant during the weaning phase. When the patient is able to maintain acceptable blood gas levels for several hours on low ventilator rates (10 to 15 breaths/minute), extubation should be attempted.

During the days after the extubation, it is important to provide chest physiotherapy to prevent airway obstruction and lung collapse caused by retained secretions. In smaller infants, the use of nasal continuous positive airway pressure (CPAP) after extubation can stabilize respiratory function and reduce the need to reinstitute mechanical ventilation.

Although it is necessary to reduce the FiO_2 as quickly as possible to prevent oxygen toxicity, it is important to maintain the PaO_2 at a level sufficient to ensure adequate tissue oxygenation and to prevent the pulmonary hypertension and cor pulmonale that can result from chronic hypoxemia. Furthermore, infants with BPD might respond with increased airway resistance to episodes of acute hypoxemia.

Because oxygen therapy does not produce respiratory depression in infants with BPD, the PaO_2 must be maintained above 50 to 55 mm Hg to prevent the effects of hypoxemia. Oxygen can be administered through a hood, tent, facemask, or nasal cannula. Because the oxygen consumption increases and the PaO_2 may decrease during feedings, it might be necessary to provide a higher FiO_2 to prevent hypoxemia.

Oxygen therapy could be required for several weeks or months. Some of these patients are discharged with oxygen therapy at home. This practice offers significant advantages, such as a better environment for the patient and cost savings, but it requires a supportive family and home environment to be accomplished safely and successfully.

Adequacy of gas exchange should be monitored continuously to avoid hypoxemia or hyperoxemia. Blood gas determinations obtained by arterial puncture are usually not reliable because the infant responds to pain with crying or apnea. Transcutaneous PO_2 electrodes are also inaccurate in these infants because they underestimate the true PaO_2. Pulse oximeters offer the most reliable estimate of arterial oxygenation and have the advantage of simplicity of use and the possibility of assessing oxygenation during feeding and crying.

Although there are no conclusive data in the literature on the optimal level of oxygenation for these infants, in general it is recommended to maintain their oxygen saturation in the range of high 80s to low or mid 90s. This range should minimize the risk of oxygen exposure and toxicity and prevent hypoxemia that can lead to pulmonary hypertension and poor weight gain.[2,54,55] Several international trials evaluating lower saturations ranges are underway.

Fluid Management

Infants with BPD tolerate excessive or even normal amounts of fluid intake poorly and, as mentioned earlier, have a marked tendency to accumulate excessive interstitial fluid in the lung. This excess can lead to a deterioration of their pulmonary function, with exaggeration of hypoxemia and hypercapnia and longer ventilator dependency.

To reduce lung fluid in infants with BPD, water and salt intake should be limited to the minimum required to provide the calories necessary for metabolic needs and growth. When increased lung water persists despite fluid restriction, diuretic therapy can be used successfully. The use of diuretics in infants with BPD is associated with an acute improvement in lung compliance and decrease in resistance, but blood gases do not always show improvement. Similar effects have been reported after the administration of furosemide by nebulization. The reduction in pulmonary capillary pressure observed after furosemide administration is not only due to the increased elimination of sodium and water but seems, in part, secondary to an increase in venous capacitance and reduced pulmonary bloodflow produced by this drug. Complications of chronic diuretic therapy include potential ototoxicity, hypokalemia, hyponatremia, metabolic alkalosis, hypercalciuria with nephrocalcinosis, and hypochloremia. Some of these side effects can be reduced by using an alternate-day schedule with furosemide.

Because increased metabolic demands in infants with BPD are associated in severe cases with low arterial oxygen tension, it is important to maintain a relatively normal blood hemoglobin concentration. This may be accomplished with blood transfusions or by the administration of recombinant erythropoietin.

Bronchodilator Therapy

Infants with severe BPD have airway smooth muscle hypertrophy and airway hyperreactivity. Because hypoxia can increase airway resistance in these patients, maintenance of adequate oxygenation is important for avoiding bronchoconstriction. Bronchodilators, most of them β-agonists, administered by inhalation have been shown to reduce airway resistance in infants with BPD. However, their safety and efficacy have never been evaluated in randomized clinical trials. Their effect is usually short-lived, and many of these drugs have cardiovascular side effects such as tachycardia, hypertension, and possible arrhythmias. Because of this, it is preferred to limit their use to the management of acute exacerbations of airway obstruction.

Methylxanthines (aminophylline and caffeine) also have been shown to reduce airway resistance in these infants. These drugs have other potential beneficial effects, such as respiratory stimulation and mild diuretic effect, and aminophylline can also improve respiratory muscle contractility.

Because of the increased concentration of leukotrienes in bronchial secretions of infants with BPD, cromolyn sodium has been suggested as a drug that might reduce airway resistance, but the experience is too limited to recommend its widespread use.

Nutrition

Infants with BPD frequently have impaired growth.[34] Adequate nutrition is a key aspect of care for these infants, who have an increase in resting oxygen consumption partially caused by the elevated work of breathing. Malnutrition can delay somatic growth and the development of new alveoli, making successful weaning from mechanical ventilation less likely. The malnourished patient is also more prone to infection and oxygen toxicity.

For these reasons, an aggressive approach should be taken toward supplying a parenteral or oral caloric intake that is adequate for growth. High-calorie formulas and supplements of protein, calcium, phosphorus, and zinc can be used to maximize the intake of calories while restricting fluid intake to prevent congestive heart failure and pulmonary edema. If for any reason enteral nutrition is precluded for more than 3 or 4 days, parenteral alimentation with glucose, amino acids, and fat should be substituted until the gastrointestinal tract again becomes functional.

Adequacy of nutrition should be closely monitored, and growth charts for weight, head circumference, and height must be kept. Other means of assessment include arm anthropometry to determine muscle mass and fat deposits and measurement of serum levels of albumin. Rib fractures noted on routine chest radiographs together with generalized bone demineralization are often observed in infants with BPD and are usually a manifestation of rickets. The cause could relate to dietary or parenteral deficiency of calcium or vitamin D or to the calciuria resulting from long-term diuretic therapy. Administration of extra calcium and vitamin D is necessary to prevent rickets in these infants.

In infants with established BPD, the use of a high-fat formula can increase the caloric intake and reduce carbon dioxide production. Infants who receive exclusively parenteral nutrition for prolonged periods are more susceptible to developing deficiency of specific nutrients, such as vitamins A and E, and trace elements such as iron, copper, zinc, and selenium, all of which play a role in antioxidant function, protection against infection, and lung repair.

Decreased caloric intake potentiates oxygen-induced lung damage and can interfere with cell multiplication and lung growth. Deficiency of sulfur-containing amino acids could also affect lung levels of glutathione, a potent antioxidant. Infants with severe BPD have been shown to have lower plasma levels of vitamin A, and a deficiency of this vitamin in experimental animals results in loss of ciliated epithelium and squamous metaplasia in the airways, changes similar to those observed in BPD. Clinical trials in preterm infants with severe RDS suggest that maintenance of normal plasma levels of vitamin A reduces the incidence and severity of BPD.[56]

Gastroesophageal reflux is often observed in infants with BPD, and when severe, may contribute to the chronic inflammatory process and lung damage. When severe reflux is documented, antireflux management might be indicated to alleviate the respiratory symptoms.

Control of Infection

See also Chapter 39.

Any infection can have serious consequences for the child with BPD, and bacterial, viral, or fungal infection generally results in profound setback. As a result, the child must be closely watched for early evidence of infection. Tracheal secretions are collected for culture and Gram stain or if a change in the quality and quantity of secretions indicates possible infection. A complete blood count, blood culture, and chest radiograph are obtained if pneumonia is suspected.

Although it is difficult to distinguish between colonization of the airway and true infection, this distinction is important because overtreatment with antibiotics could result in the emergence of resistant and more virulent organisms. Selection of antibiotics is based on the sensitivity of the implicated organism, and treatment is continued until the infection has been controlled. Measures to prevent pulmonary nosocomial infection are important. These include careful handwashing before handling the airway, maintenance of sterility of the respiratory equipment, and isolation from individuals with respiratory infections.

Corticosteroids

Because of the importance of inflammation in the pathogenesis of BPD, there has been interest in exogenous administration of corticosteroids during the early stages of the disease to reduce its progression. Several reports showed rapid improvement in lung function after the administration of steroids, facilitating weaning from the ventilator when compared with controls who received placebo.[3,19] The optimal age of treatment, dose schedule, and duration of therapy have not been established, and long-term respiratory outcome has not clearly improved in treated infants.[1,10,30,46]

Many mechanisms for the beneficial effect of steroids in BPD have been proposed. They include enhanced production of surfactant and antioxidant enzymes, decreased bronchospasm, decreased pulmonary and bronchial edema and fibrosis, improved vitamin A status, and decreased responses of inflammatory cells and mediators in the injured lung.

Potential complications of prolonged steroid therapy include masking the signs of infection, arterial hypertension, hyperglycemia, increased proteolysis, adrenocortical suppression, somatic and lung growth suppression, and hypertrophic cardiomyopathy. In addition, long-term follow-up studies suggest that infants who received postnatal steroid therapy have worse neurologic outcome than control infants.[45,70] Because of the seriousness of some of these complications, the American Academy of Pediatrics does not recommend the use of steroids except as part of a clinical trial or in the presence of life-threatening disease with parental consent. It remains to be seen whether treatment with shorter courses and lower doses beyond the first week of life offers significant advantage.

Controversy still exists regarding the possible beneficial effects of lower steroid doses and shorter durations of treatment. Doyle and colleagues studied low-dose dexamethasone after the first week of life and showed shorter duration of intubation among ventilator-dependent infants with extremely low birthweight (ELBW), without any obvious short-term complications, reopening the debate regarding the potential role of low-dose dexamethasone therapy specifically for infants at high risk for BPD.[22] Furthermore, a recent metaregression analysis reported a significant effect modification by risk for BPD. With a risk for BPD below 35%, corticosteroid treatment increased the chance of death or cerebral palsy, whereas when the risk for BPD exceeded 65%, corticosteroid treatment reduced this risk.[23] Wilson-Costello and colleagues examined the impact of dexamethasone dose, and timing in a large cohort of infants with ELBW.[69] Overall 16% of the cohort was exposed to dexamethasone. The authors confirmed the previous observation by Doyle and colleagues that the risk of the composite outcome of death or neurodevelopmental impairment was modified by the predicted risk of BPD[22]. Neonates at more than 50% predicted risk of BPD experienced less harm than those at lower risk (high-risk odds ratio [OR], 1.9; 95% confidence interval [CI], 1.4-2.6; low-risk OR, 2.9; 95% CI, 1.8-4.8). Infants at even higher predicted risk of BPD crossed a point where the risk of postnatal steroid treatment was offset by the risk of deteriorating pulmonary status and its associated detrimental effects. Thus, the optimal corticosteroid type and the optimal dose are unknown, but it appears that the avoidance of steroids may in fact be detrimental to a class of infants at high risk for BPD.

In an attempt to induce the beneficial effects on the lung but minimize the systemic side effects, steroids have been administered by nebulization to a group of ventilator-dependent infants. This therapy resulted in a significant improvement in lung compliance and resistance only after 3 weeks of treatment. A subsequent study showed that inhaled steroids could reduce the need for systemic steroids, reducing the side effects associated with prolonged systemic therapy.[18] Data on topical steroids are not conclusive enough to recommend routine use of this therapy.

Pulmonary Vasodilators

Oxygen therapy to prevent hypoxemia is probably the most effective treatment to reduce pulmonary hypertension in these infants. Because pulmonary vascular resistance is extremely sensitive to changes in alveolar P_{O_2} in infants with BPD, it is important to ensure normal oxygenation not only when the infant is asleep but also when the infant is performing physical activity, such as feeding and crying.

In infants with severe pulmonary hypertension and cor pulmonale, the calcium channel blocker nifedipine decreases pulmonary vascular resistance. This drug is also a systemic vasodilator and can produce a depression of myocardial contractility. Its safety and long-term efficacy in these infants has not been established. Inhaled nitric oxide (iNO) is another alternative to reduce pulmonary vascular resistance in infants with severe pulmonary hypertension. Data are emerging on the potential role of iNO in the prevention of BPD. Trials that administered nitric oxide early in life for brief durations did not improve pulmonary outcomes at 2 years of age, although they did suggest some neuroprotection on imaging studies, and in the study by Mestan and coworkers.[37,39,51] In contrast, the NO CLD trial led by Ballard and coworkers found that treatment of ventilated preterm infants at a mean age of 16 days for 24 days significantly improved the likelihood of survival without BPD at 36 weeks of postmenstrual age.[6,7] Compared with infants who received placebo gas, infants who were treated with iNO were hospitalized for fewer days, needed supplemental oxygen for a shorter period, and had less severe disease. In addition, treated infants required fewer days of ventilatory support and hospitalization,[72] and were less likely to require treatment with pulmonary medications in the first year.[32] There was no evidence of adverse neurodevelopmental outcomes at 2 years of age.[61] Thus, while nitric oxide may prevent BPD, likely by modifying alveolarization and angiogenesis, its clinical role remains to be determined.

Infant Stimulation

The infant with severe BPD could be ventilator dependent for many months and thus deprived of normal parental stimulation. Developmental delays are common and are compounded if any gross neurologic disability exists. A well-organized program of infant stimulation can help the infant achieve maximum potential. Such a program instructs the caretakers in helping the infant with various social, language, cognitive, and motor skills (see also Chapter 43). As a child grows, speech therapy is useful in teaching communication skills, which are especially important for children with a tracheostomy. Beanbag chairs, strollers, and other adaptive tools are employed to mobilize the child and teach gross motor skills. Progress is monitored by periodic developmental evaluations, and emphasis is placed on areas in which delay is evident.

Parental Support

The parents of an infant with severe BPD lose considerable control of their child to the hospital staff, particularly in areas related to medical care. Parental participation is critical for the child's development and for establishment of normal relationships. Therefore, parents are encouraged to visit as frequently as possible and to participate in the day-to-day care of their child. They are educated about relevant medical equipment and procedures. In time many are able to assume complete responsibility for procedures such as chest physiotherapy and tracheal suctioning in addition to holding and playing with their child. During the prolonged hospitalization every effort must be made to assign a permanent physician and nursing team to oversee the child's care and be available for continuing parental support. Parental support groups may also be a valuable resource for these families.

OUTCOME

The outcome of infants with BPD has improved in part because of better management, but mainly because of the milder presentation of the disease.

The mortality rate for infants with BPD is low; when death occurs it is usually a result of respiratory failure, intercurrent infections, or intractable pulmonary hypertension and cor pulmonale. With adequate nutrition, somatic growth, and control of infection and heart failure, gradual improvement in pulmonary function may be accompanied by resolution of cor pulmonale and radiographic evidence of healing.

Lower respiratory tract infections are common during the first year of life in patients with BPD. Among survivors of BPD, hospitalizations for episodes of wheezing suggestive of bronchiolitis or asthma are common during the first 2 years of life, and infection with respiratory syncytial virus (RSV) can be life threatening. The American Academy of Pediatrics has recommended that all infants with BPD receive palivizumab during RSV season (see Chapter 39, Part 4). Acute radiographic evidence of hyperinflation can be difficult to appreciate in infants with severe BPD who generally are already in a state of pulmonary hyperinflation. Such episodes of bronchiolitis are often accompanied by focal, transient areas of atelectasis.

Pulmonary function studies of infants with a history of severe BPD indicate that pulmonary function may be impaired for many years even though the infants may be asymptomatic.[12,29,36,48] Northway and associates have reevaluated pulmonary function in their original cohort of infants with severe BPD reported in 1967.[42] At a mean age of 18 years, these adolescents and young adults still exhibited some evidence of pulmonary dysfunction, including airway obstruction and hyperactivity as well as hyperinflation. The ultimate clinical consequences of these findings remain to be determined, but most long-term studies suggest that with growth, pulmonary function tends to normalize.

Infants with severe BPD also have more neurodevelopmental sequelae when compared with similar control groups, and they exhibit transiently impaired growth curves. These neurodevelopmental and pulmonary impairments persist at 8 years of age, with 54% requiring special education classes compared with 37% of survivors born at very low birthweight without BPD.[21,53] Neurodevelopmental prognosis also depends on the severity of the BPD and on other associated risk factors that could be present in these infants. Infants with BPD also have been reported to have an increased risk for sudden infant death, but the evidence for this is not conclusive.

PREVENTION

The incidence of severe BPD has decreased, but there is a wide variation in incidence among different centers.[4,62] This variation suggests that certain steps in the management of preterm infants can influence the risk of BPD, although attempts to modify BPD have met with variable levels of success.[47] Because many factors play a role in the pathogenesis of BPD, it is important to focus on all of them and try to prevent as many as possible.

Prevention of BPD should start prenatally by attempting to prolong pregnancy as much as possible in cases of preterm labor. By postponing birth a few days or weeks, it is possible to substantially reduce the severity of RDS and the risk of BPD in the offspring. When birth is imminent, one effective means of reducing the risk of BPD in the infant is by administering antenatal steroids. Steroid administration reduces the incidence and severity of RDS, although the effect on the incidence of BPD has been less consistent.[59]

After birth, the effort should be initially directed to reduce as much as possible the infant's exposure to high airway pressures and FiO_2. Although the use of early CPAP to reduce the use of mechanical ventilation has not been shown to reduce BPD, a conservative indication of mechanical ventilation and minimization of airway pressures and duration of IPPV are considered important steps to reduce lung damage and the incidence of BPD. The use of high-frequency ventilation has not been shown to be effective in reducing BPD in infants but data obtained in experimental animals suggest that high-frequency ventilation can reduce lung injury. Fluid restriction and early closure of a symptomatic PDA are important as is prevention of pulmonary and systemic infections. Proper nutrition and adequate supply of substrates that are important for the antioxidant mechanisms must be provided early in the course of the respiratory failure. The administration of caffeine to wean infants from mechanical ventilation has been associated with a significant reduction in the incidence of BPD.[50]

Exogenous administration of specific antioxidants, such as superoxide dismutase, metalloporphyrins, or inducers of the cytochrome P-450 system, is still experimental but could become an important part of BPD prevention in the future.[14] The possibility that exogenous surfactant administration to infants with RDS could reduce the incidence of BPD is still controversial. Large controlled trials have not shown a significant effect of exogenous surfactant administration on the incidence of BPD alone, but when combined with survival, infants who received surfactant had a significant advantage.

Although it can be expected that surfactant will reduce the incidence of BPD in infants who previously developed severe RDS, it is unlikely that it will have a significant effect on the BPD that occurs with increasing frequency in infants with extremely low birthweight who require prolonged IPPV because of poor respiratory effort rather than severe RDS. In these infants, a conservative use of mechanical ventilation, combined with an aggressive approach to close the PDA and efforts to reduce the risk of nosocomial infections, are probably the most effective ways to reduce the incidence and severity of BPD.

PART 8

Therapy for Cardiorespiratory Failure

Eileen K. Stork

Assisted ventilation and oxygen therapy remain the standard of care for neonatal respiratory failure. A few term and preterm infants with a wide range of diagnoses develop intractable cardiorespiratory failure despite maximal ventilatory support. In these patients, severe pulmonary hypertension often contributes to persistent hypoxemia.

Two unique therapies for such patients are presented in this section: extracorporeal membrane oxygenation (ECMO), which is now well established as a rescue therapy for intractable respiratory failure in neonates, and inhaled nitric oxide (iNO), a noninvasive inhalational therapy that can elicit selective pulmonary vasodilation.

EXTRACORPOREAL MEMBRANE OXYGENATION

In ECMO, techniques of cardiopulmonary bypass, modified from those originally developed for open heart surgery, are used over a prolonged period to support heart and lung function. In newborns with hypoxic respiratory failure, this allows the lungs to rest and recover, and prevents the often damaging effects of aggressive artificial ventilation and 100% FiO_2.

ECMO offers support for term or near-term neonates with life-threatening cardiopulmonary disease. Because of serious inherent risks, such as systemic and intracranial hemorrhage, the procedure is currently reserved for neonates with reversible pulmonary disease in whom trials of conventional or high-frequency ventilation as well as inhaled nitric oxide have failed.

Several randomized trials have demonstrated improved survival in infants supported with ECMO. The most rigorous prospective, randomized trial was conducted in the United Kingdom, where 185 infants with severe respiratory failure were randomized to ECMO or conventional ventilatory management.[18] Survival in the ECMO-treated patients was 68% compared with 41% survival in the control arm ($P = .0005$), equivalent to one extra survivor for every three or four infants allocated to ECMO. Neurologic outcome was similar among survivors of either treatment arm, making it unlikely that ECMO contributed any added morbidity to this cohort of critically ill newborns.

Respiratory disease in the newborn is often complicated by persistent pulmonary hypertension of the neonate (PPHN), also called persistent fetal circulation. In this circumstance the pulmonary vascular resistance approaches or exceeds systemic vascular resistance, offering significant impedance to pulmonary bloodflow. Desaturated blood returning to the right heart is shunted to the systemic circulation (following the path of least resistance) across two persistent fetal channels, the patent ductus arteriosus (PDA), and the foramen ovale, resulting in marked cyanosis.

The clinical course of such infants is variable, depending on the severity of the underlying disease process and the degree to which PPHN contributes to the cyanosis. Diagnoses associated with severe hypoxic respiratory failure in neonates include meconium aspiration syndrome (MAS), respiratory distress syndrome (RDS), group B streptococcal sepsis and pneumonia, congenital diaphragmatic hernia (CDH), and asphyxia neonatorum. Idiopathic pulmonary hypertension is sometimes seen in patients who exhibit minimal or no lung disease and have clear chest radiographs. The International Extracorporeal Life Support Organization (ELSO) Registry reports the distribution of primary diagnoses and survival for patients undergoing bypass; data are shown in Figure 44-87.[17]

Traditional therapy for respiratory failure complicated by PPHN consists of the use of oxygen, mechanical ventilation, alkalosis, and pharmacologic vasodilators in an attempt to decrease pulmonary vascular resistance and increase bloodflow to the lungs. iNO is a selective pulmonary vasodilator that enhances pulmonary bloodflow and improves oxygenation in PPHN. For infants who do not respond to these measures, however, ECMO can be useful therapy.

Basic Techniques

The standard ECMO procedure used in most newborn intensive care units today is venoarterial (VA) bypass because it provides both pulmonary and cardiac support. The right atrium is cannulated via the right internal jugular vein with a Silastic or polyvinyl chloride catheter (10- to 14-French diameter); blood is siphoned to a level below the heart where a roller head or centrifugal pump circulates the blood through the artificial lung. These pumps are servoregulated to slow or shut down if venous return is not adequate to meet circuit flow demands. As the blood circulates through the artificial lung, gas exchange occurs against a filtered mixture of oxygen

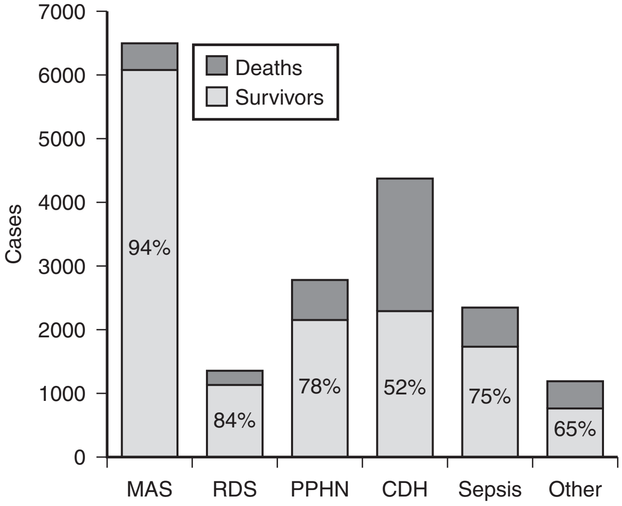

Figure 44–87. International ECMO experience (through January 2010). Data are derived from the Extracorporeal Life Support Organization Registry. MAS, meconium aspiration syndrome; RDS, respiratory distress syndrome; PPHN, persistent pulmonary hypertension of the neonate; CDH, congenital diaphragmatic hernia,

and CO_2. The most common artificial lung currently used in neonates is a 0.6 or 0.8 m^2, thin, gas-permeable silicone sheet membrane that serves as a blood-gas interface, similar to the alveolar capillary membrane. Countercurrent flow of blood and gas on opposite sides of the membrane allows for effective diffusion of gases between the blood and gas phases. The larger the patient, the larger the membrane lung must be to provide adequate gas exchange. In older children (more than 10 kg) and adults, a smaller, but more efficient, hollow fiber membrane lung (Quadrox D) has largely replaced the sheet membranes used for the past 25 years. Advantages of this newer artificial lung include a low priming volume and reduced blood/foreign surface area contact. This new generation of artificial lung also incorporates a heat exchanger to rewarm the oxygenated blood returning to the patient. Neonatal sized Quadrox membrane lungs for neonates and will be available in late 2010.

Oxygenation can be regulated by varying bloodflow through the ECMO circuit. The higher the volume of cardiac output diverted through the membrane lung, the better the oxygen delivery from the ECMO circuit. Oxygenated blood exiting the artificial lung is returned to the infant via an 8- to 12-French catheter positioned in the ascending aortic arch through a right common carotid artery cannulation.

Bloodflow through the ECMO circuit, at a rate of 90 to 120 mL/kg per minute, is usually adequate to provide excellent cardiac and respiratory support with maintenance of adequate blood pressure and oxygenation. Arterial wave dampening with narrowed pulse pressure is noticeable at flow rates approaching the infant's cardiac output because the ECMO circuit provides relatively nonpulsatile bloodflow. Pressor support, vasodilators, and paralytic agents can usually be stopped while the infant is on venoarterial (VA) ECMO support because perfusion pressure from the pump largely replaces cardiac output. Systemic anticoagulation therapy with unfractionated heparin is administered for the duration of the bypass procedure to prevent clotting in the circuit and possible thromboembolization. Activated clotting times are measured hourly and are maintained within a range of 180 to 240 seconds.

Once the infant is placed on ECMO, ventilator and oxygen support is reduced to a minimum to avoid any further barotrauma or oxygen toxicity to the lung. Infants can be maintained in room air with a peak inspiratory pressure (PIP) of 14 to 20 cm H_2O and a ventilator rate (IMV) of 12 to 20 for the duration of VA bypass. If volume ventilation is preferred, 3 to 6 mL/kg tidal volume is used to effect mild chest rise with each delivered breath. This helps maintain lung inflation and allows for continued pulmonary toilet. The respiratory status of the infant can be monitored with intermittent arterial blood gases obtained from the umbilical or peripheral arterial line. An oxygen saturation electrode inserted on the venous side of the circuit allows continuous monitoring of the mixed venous saturation at the level of the superior vena cava and right atrium. A mixed venous saturation of 70% or greater reflects adequate oxygen delivery.

As lung function improves or pulmonary hypertension abates, or both, the mixed venous saturation and partial pressure of arterial oxygen (PaO_2) rise above the baseline oxygenation provided through the artificial lung. Bloodflow through the artificial circuit can then be decreased in small increments (10 to 20 mL) while mixed venous and arterial oxygenation remain adequate. When ECMO flow has been reduced to 10 to 20 mL/kg per minute, the infant can be weaned from extracorporeal support.

Increased ventilator support is provided as the patient approaches decannulation. Bypass support may be required for 2 to 45 days with an average need for 8.9 days of support.[17] Continued ventilator support following ECMO can be quite variable (days to weeks) depending on the underlying cause of respiratory/cardiac failure, as well as the degree of barotrauma incurred before initiation of ECMO.

In most ECMO centers, the right carotid artery and internal jugular vein are permanently ligated at decannulation. This approach is technically easier and prevents any concern about acute embolic complications associated with vascular reconstruction. However, some surgeons reanastomose these vessels if the patient has been on bypass less than 10 days to prevent future ischemic risks to the developing newborn brain as well as during later adult life. Studies show no disadvantage to this approach. Magnetic resonance (MR) angiograms and Doppler flow studies confirm good antegrade flow through the reconstructed carotid artery postoperatively in the majority of these infants. However, long-term patency of the reconstructed carotid remains a question. Ultrasound vascular studies in children up to 5 years of age with reconstructed carotid arteries confirm good antegrade flow through the vessels in most cases, with no embolic sequelae reported.[16] Neurodevelopmental outcome and neuroimaging were equally favorable. Longer-term neurologic follow-up of these patients compared with ECMO survivors with carotid ligation is of interest to surgeons and neonatologists alike. Carotid artery ligation carries a small but definite risk for development of ischemic sequelae during VA bypass, whereas the risk for future ischemic stroke remains unknown.

Venovenous Extracorporeal Membrane Oxygenation

A growing experience supports the ability of venovenous ECMO to provide adequate oxygen delivery in patients with serious respiratory failure, but adequate heart function. In adults this technique usually involves draining desaturated blood from the right atrium and returning oxygenated blood through the femoral vein.

Venovenous (VV) bypass in infants has been greatly improved by the development of double-lumen catheters of varying sizes (12, 15, 18 French) that allow bypass support with cannulation of the right atrium alone. Desaturated blood is withdrawn from the right atrium through the outer fenestrated venous catheter wall. Oxygenated blood from the ECMO circuit is returned to the inner arterial catheter, which is angled to direct blood across the tricuspid valve. Higher flow rates are required to maintain adequate oxygen delivery with VV bypass because of recirculation of desaturated and oxygenated blood within the right atrial chamber.

Advantages of VV bypass include avoidance of carotid artery cannulation and maintenance of pulmonary bloodflow. The major disadvantage is that, unlike VA bypass, VV ECMO does not provide cardiac support. Oxygen delivery in VV bypass remains dependent on native cardiac output.

Survival data, complication rate, and length of bypass support compare favorably with those of VA bypass cases. The ELSO Registry reports that more than 6000 newborns have undergone VV bypass with only 11% requiring conversion to venoarterial support.[17] Because it avoids carotid ligation, VV bypass has enormous appeal and has become the treatment of choice in newborns with adequate cardiac function.

Personnel Needs

ECMO is the most labor-intensive procedure in the neonatal intensive care unit (NICU). Specialists trained in managing patients on ECMO must remain at the patient's bedside for the duration of bypass. In addition to monitoring the infant's respiratory status, specialists must regulate the rates of blood and gas flow through the extracorporeal circuit to meet the infant's respiratory demands. They must adjust anticoagulation by measuring the activated clotting time in the blood every 30 to 60 minutes and titrate the heparin infusion accordingly. Additionally, they must evaluate the patient for bleeding and replace losses appropriately. The specialists can be physicians, nurses, perfusionists, or respiratory therapists who have completed extensive training in perfusion support.

An ECMO physician trained in the clinical management of bypass patients must always be readily available for consultation, especially in case of mechanical failure or acute clinical decompensation. Additional support services required include 24-hour availability of personnel trained in radiology (ultrasonography), pediatric surgery, neurology, genetics, cardiology, and cardiothoracic surgery. The expertise and personnel needed to support these patients are extensive and costly.

Criteria for Patient Selection

The cumulative experience of many ECMO centers has resulted in the establishment of criteria that are currently used to decide whether ECMO support is appropriate.[62] These are described in Box 44-14.

GESTATIONAL AGE OF 34 WEEKS OR OLDER

Preterm newborns with respiratory failure carry a higher risk for intracranial hemorrhage (ICH) compared with term infants at baseline, and this risk is heightened with systemic heparinization required during ECMO support. Furthermore, changes in cerebral bloodflow patterns associated with cardiopulmonary bypass can also place the immature brain at increased risk for bleeding.

BOX 44-14 Patient Selection Criteria for Neonatal Extracorporeal Membrane Oxygenation [62]

- Gestational age of 34 weeks or older
- Normal cranial ultrasound (grade I intraventricular hemorrhage is a relative contraindication)
- Absence of complex congenital heart disease
- Less than 10 to 14 days of assisted ventilation
- Reversible lung disease, including congenital diaphragmatic hernia
- Failure of maximum medical therapy
- No lethal congenital anomalies or evidence of irreversible brain damage

In the early ECMO trials, premature infants less than 35 weeks' gestation had an 89% incidence of spontaneous ICH associated with heparinization.[6] Subsequent studies, (all retrospective) revisiting this issue, reported improvement in outcome, but confirmed increasing rates of ICH as gestational age decreases, with the incidence of ICH approaching 50% at gestational ages younger than 34 weeks.[62]

Technical refinements in bypass support have made ECMO possible for infants weighing as little as 1800 g. However, gestational age remains a strong predictor of ICH risk. In a recent study, postconceptional age (PCA) proved to be the highest predictor for ICH risk. In a retrospective study of 1524 neonates less than 37 weeks' gestation treated with ECMO between 1992 and 2000, ICH developed in 26% of patients younger than 32 weeks' PCA compared with 6% of patients with PCA of 38 weeks ($P = .004$).[26] Neurodevelopmental outcome in surviving preterm infants treated with ECMO in the first 2 weeks of life has not been well studied. This, together with the higher morbidity and mortality among ECMO-treated preterm infants, forms the basis of the recommendation that ECMO support be reserved for term and near-term infants.

NO MAJOR INTRACRANIAL HEMORRHAGE

The catastrophic extension of intracranial bleeds, along with the attendant neurologic sequelae, is the primary risk reported in the early series of Bartlett and associates.[6] Some centers have successfully managed infants with grade I or stable grade II intraventricular hemorrhage on bypass using a minimal heparin dosage to lessen bleeding complications and high ECMO flow rates to prevent clotting in the extracorporeal circuit. Uncontrolled bleeding from surgical wounds, chest tubes, or other sites also worsens with heparin therapy and is a contraindication to ECMO. The septic infant is of concern in this regard because of the commonly associated coagulopathy. Although these infants have a higher risk of bleeding complications on ECMO, meticulous correction of their coagulopathy and careful heparin management have allowed these infants to be successfully treated.[17]

ABSENCE OF COMPLEX CONGENITAL HEART DISEASE

Infants in severe respiratory failure must have an echocardiogram to rule out congenital heart disease as the underlying cause for refractory hypoxemia. In some instances, the degree of hypoxemia is not easily explained based on the heart lesion alone (e.g., in a newborn with an atrioventricular canal complicated by meconium aspiration or sepsis). ECMO can provide cardiovascular support to stabilize such a patient until the reversible component of the lung disease is no longer an issue, rendering the baby a more viable surgical candidate at some later date.

Similarly, an infant with suspected cyanotic congenital heart disease may present to an ECMO center with profound cyanosis and cardiogenic shock despite the use of prostaglandins and inotropes. Preoperative ECMO can stabilize such infants who are believed to have reparable cardiac defects, but who are deemed to be poor surgical candidates by virtue of their clinical instability. Both venovenous and venoarterial ECMO have been used preoperatively in infants with cyanotic congenital heart disease and cardiovascular instability.[31,34] Indications for ECMO include arterial saturations of 60% or less accompanied by hypotension and metabolic acidosis unresponsive to mechanical ventilation and pharmacologic support with inotropes and vasodilators. For most infants presenting with isolated cyanotic congenital heart disease, however, prompt surgical intervention, not ECMO, is the obvious treatment of choice.

LESS THAN 10 TO 14 DAYS OF ASSISTED VENTILATION

Although ECMO can support cardiovascular function for days to weeks, it does not reverse serious preexisting pulmonary damage. In early studies infants subjected to prolonged mechanical ventilation with high pressures and FiO_2 before ECMO suffered extensive barotrauma and did not recover despite prolonged support (more than 2 weeks) on bypass.[6] Severe bronchopulmonary dysplasia (BPD), or inability to wean from ECMO support, was the result. Infants who have recovered from BPD, however, are eligible for ECMO later in life. BPD survivors have been placed on ECMO in later infancy or toddlerhood for life-threatening bronchiolitis with good survival results: 59 of 76 (78%) patients in one study.[17] One center, however, reported severe pulmonary and neurodevelopmental sequelae among four of seven survivors with BPD who required ECMO beyond the neonatal period.[28]

Recent changes in ventilatory management wherein lower pressure and volume settings are used to avoid barotrauma (permissive hypercapnea or gentle ventilation) may protect the neonatal lung from irreversible damage for longer periods than earlier studies suggested. Use of surfactant and inhaled nitric oxide (iNO) may also blunt ventilator-induced lung injury. Nevertheless, the longer an infant is ventilated with high FiO_2 before initiating ECMO, the longer that infant will take to recover, owing to the barotrauma and oxygen toxicity superimposed upon the infant's underlying lung disease. Therefore, if a patient fails to respond favorably to respiratory measures available, ECMO support should be considered expeditiously.

REVERSIBLE LUNG DISEASE

Using reversible lung disease as a criterion to determine whether to use ECMO is intended to exclude infants with severe lung hypoplasia incompatible with life. Patients with marked renal dysplasia and prolonged oligohydramnios, large congenital diaphragmatic hernia (CDH) presenting in extremis at birth, and hydrops fetalis fall into this category. However, infants with respiratory failure in all these categories have survived with ECMO support, making the judgment of irreversible lung disease in the newborn extremely problematic.

The Dilemma of Congenital Diaphragmatic Hernia

CDH is defined as an anatomic defect in the diaphragm that permits abdominal contents to herniate into the thoracic cavity. In some cases the abdominal viscera are covered with a membranous sac. The incidence of CDH is 1 in 2500 live births. The type of hernia depends on the location of the diaphragmatic defect. The most common is the posterolateral hernia, also called the *Bochdalek hernia*, which accounts for 90% to 95% of CDH cases. The defect occurs more frequently on the left side of the diaphragm (78% to 84%) than on the right side (14% to 20%), whereas bilateral hernias occur rarely (0.9% to 2%).[23]

In CDH, the fetal lungs have a reduced number of arterioles and conducting airways. There are fewer alveoli, thickened alveolar walls, and increased interstitial tissue resulting in markedly diminished alveolar airspace and gas exchange surface area. Vascular development parallels that of the airways. There are a reduced number of vessels, adventitial thickening, medial muscle hyperplasia, and peripheral extension of the muscular layer into the smaller intra-acinary arterioles. Both lungs are affected, the ipsilateral one more than the contralateral one, and the hypoplasia is progressive beyond 30 weeks.[25] After delivery, these morphologic changes compromise effective gas exchange, resulting in respiratory failure and pulmonary hypertension. Survivors additionally suffer from variable degrees of pulmonary, gastrointestinal (gastroesophageal reflux and feeding problems), orthopedic (scoliosis, rib cage hypoplasia), and hearing and neurodevelopmental issues.

Infants with CDH who present with cyanosis and respiratory distress at delivery often suffer significant pulmonary hypoplasia, although the degree of lung restriction is difficult to assess radiographically because of the bowel contents in the chest. Volatile pulmonary hypertension in the first few days of life complicates the clinical course, even when adequate lung volume is available for gas exchange.

Infants in whom profound cyanosis develops, despite oxygen, mechanical ventilation, bowel decompression, and judicious volume and pressor support of blood pressure, make up the subset of patients with CDH for whom ECMO support is justified. As shown in Figure 44-87, CDH is the second most common diagnosis for which ECMO support is used in neonates. In the 2010 ELSO Registry (a national registry of ECMO cases), survival of newborns with CDH supported with ECMO (n = 5721) is 51%. This stands in marked contrast to the 94% survival achieved among infants with meconium aspiration treated with ECMO (n = 7438).[17]

Prenatal diagnosis of CDH is now common, but a substantial number of cases are still missed. In a prospective, population-based study of congenital anomalies in the United Kingdom, only 63 of 100 cases of CDH were diagnosed prenatally between 1997 and 2000 out of 125,380 live births. By comparison, during the same time period the prenatal diagnosis rate for hypoplastic left heart syndrome was 88% and the detection rate for gastroschisis was 94%. The prenatal diagnosis rate for all registered anomalies reported improved significantly over each 4-year epoch recorded from 1985 through 2000. Of note, termination of pregnancy for all fetal malformations rose from 23 to 47 per 10,000 registered births between 1985 and 2000.[56] In a retrospective study of 51 CDH cases recorded in the Auvergne Birth Defect Registry between 1992 and 2003, the prenatal detection rate of nonisolated CDH (detecting either the CDH or another major anomaly) was 73% while the detection rate of isolated CDH was only 45% ($P = .03$). Prenatal diagnosis in the presence of associated anomalies predicted poor outcome with survival of only 23%. Paradoxically, infants with isolated CDH who escaped prenatal detection had the highest survival rate (81%).[22,23]

The pathogenesis of CDH and the causes of pulmonary hypoplasia in this anomaly are slowly being unraveled. Nitrofen is a teratogenic herbicide (banned in the United States and United Kingdom since the 1980s) which produces CDH in rodents. When administered to pregnant dams between days 8 and 11 postconception, a high rate of CDH with associated pulmonary hypoplasia and pulmonary vascular anomalies occurs in the offspring, remarkably similar to the human malformation. A "dual hit hypothesis" has been proposed to explain the severe pulmonary hypoplasia often seen in this condition.[37] The first insult is caused by nitrofen and affects both lungs before diaphragm development is complete. The second insult affects the growth the ipsilateral lung due to compression of that lung by herniated viscera. The origin of the diaphragmatic defect lies in the disruption of the mesenchymal substrata of the pleuroperitoneal folds which form the scaffold for the eventual migration of muscular precursor cells into the nacent diaphragm. In human embryology this would point to a defect as early as 4 to 5 weeks' gestation, long before the formation of the "muscular" diaphragm.[12,50]

A defect in the retinoid signaling pathway, specifically, inhibition of retinal dehydrogenase-2 (Raldh2), has been proposed as the likely etiology of the embryonic disruption resulting in CDH.[23,24,32,50] Retinoids play a central role during embryogenesis and lung development in particular. During early lung morphogenesis, retinoic acid promotes mesodermal proliferation and induces fibroblast growth factor expression in the foregut. Retinoic acid is decreased in nitrofen-induced hypoplastic lungs in rodents. Furthermore, coadministration of large doses of vitamin A (25,000 units) and nitrofin to pregnant rodent dams reduces the incidence of CDH by 15% to 30% and attenuates lung hypoplasia, suggesting that the teratogenic effect of nitrofen on the embryonic lung and diaphragm is mediated through suppression of the retinoic pathway. Right-sided diaphragmatic hernias are also seen in offspring of dams fed a vitamin A–deficient diet. The incidence of herniation is decreased when vitamin A is introduced into the diet at midgestation.[24]

Human infants with CDH have a 40% to 60% risk for major nonpulmonary anomalies, including serious cardiac malformations.[58] Renal, central nervous system, and gastrointestinal anomalies are also reported. To date, a genetic role has not been described in isolated CDH. However, the 2% recurrence rate and association of chromosomal anomalies in 10% of nonisolated CDH cases (CDH+) suggests that there is a genetic component to this malformation. Some cases of CDH+ are associated with aneuploidy, including trisomies 13, 18, 21 and Turner syndrome (45 XO).[32,58] Structural chromosomal anomalies, including deletions, inversions, duplications, and translocations are also reported.[58] Genetic analysis has identified a CDH critical region on chromosome 15q26, which codes for four genes involved in diaphragmatic morphogenesis.[12] Microdeletions in this region have been described in several patients with nonisolated CDH and are associated with very high mortality. Other CDH "hot spots" include 1q41-q42, 3q22, 4p16, 8p23, 8q22, 11p13. Haploinsufficiency or decreased expression of one or more genes encoded in these regions may cause or predispose to the development of CDH.[32,58]

In patients with CDH for whom a syndrome diagnosis can be provided, the most frequent is Fryns syndrome, which has an autosomal recessive inheritance pattern.[32] Other phenotypic variations of Fryns syndrome have also been linked to microdeletions in the chromosomal regions mentioned earlier.

For all the reasons discussed, amniocentesis for chromosomal analysis is recommended in all cases of CDH diagnosed antenatally. After birth, G-banded chromosomal analysis should be performed in all cases of CDH, including those who had amniocentesis. Furthermore, in nonisolated cases of CDH, array-based comparative genomic hybridization (aCGH) should also be considered because this technique is useful for identifying small chromosomal deletions and duplications below the resolution of G-band chromosomal analysis.[23,58]

Infants delivered at or near term with isolated CDH have the best prognoses, with 68% to 80% overall survival in tertiary care centers within the U.S. Among infants with isolated CDH identified in utero, liver herniation into the fetal chest and low lung area-to-head circumference ratio (LHR) < 1.4 in the contralateral lung reflect an especially high risk cohort.[25] Both findings predict a marked degree of lung hypoplasia and high mortality risk. Fetal surgery intervention has been actively studied in this unique group of CDH patients. Using a novel tracheal occlusion technique, this pioneering procedure has been shown in animal models of CDH to induce often dramatic growth of the hypoplastic left lung.[14]

However, in a prospective, randomized trial in human infants with isolated left CDH, fetal tracheal occlusion did not improve survival.[27] Infants enrolled in this study between 22 and 27 weeks' gestation all had liver herniation into the left chest and LHR less than 1.4 reflecting significant pulmonary hypoplasia. Eight of 11 (73%) infants treated with fetal surgery survived, compared with 10 of 13 (77%) infants receiving standard care at a tertiary care NICU with ECMO available. Moreover, preterm delivery (mean 31.8 weeks) was more common in the fetal intervention group, although rates of neonatal morbidity reportedly did not differ between the groups.

In addition to the fetal surgery centers in the United States, three European fetal surgical centers (Belgium, Spain, and the United Kingdom) continue to refine selection criteria and surgical technique in the performance of fetal tracheal occlusion (FETO).[14,15,60] Following epidural anesthesia in the mother, along with nifedipine tocolysis and fentanyl/pancuronium anesthesia in the fetus, investigators insert a single 3.3-mm cannula through the uterine wall and into the fetus' upper airway. An inflatable balloon is inserted between the vocal cords and carina to block the egress of lung fluid and thus distend the diminutive left lung. FETO is performed ideally between 26 and 28 weeks' gestation with reversal of the tracheal occlusion planned at 34 weeks unless preterm labor intervenes. The average gestation at delivery following this procedure is 33.5 weeks with 70% delivering beyond 32 weeks.[36,60] The European FETO centers offer prenatal intervention when the degree of pulmonary hypoplasia is severe, reflected by an LHR of less than 1.0 along with liver herniation in the chest. Survival in this cohort is reportedly only 15% with expected management. Following FETO, survival improved to 61.5% in 13 infants with fetal LHR of

0.6 to 0.7, and to 77.8% in 9 infants with LHR of 0.8 to 0.9.[36] A randomized, controlled trial by the European Consortium is under discussion.

The postnatal management of CDH has changed considerably in the past several years. For one thing, CDH is no longer treated as a surgical emergency. The timing of surgical repair is usually delayed until the patient's condition is stabilized with regard to oxygenation, blood pressure, and acid-base status, sometimes for a period of several days. Two prospective studies of delayed versus immediate repair failed to show any survival advantage. Conversely, these studies did not show any adverse outcomes associated with delayed surgery.[61] The CDH Study Group, a consortium of 62 international centers tracking the outcome of patients with CDH, reports that surgical repair is now accomplished at an average of 73 hours of life in newborns not requiring ECMO support.[10]

Surfactant treatment in CDH has been used in several tertiary care nurseries based on preliminary reports of surfactant deficiency in animal models of CDH and a few human case series, even at term gestation. However, a large retrospective study has failed to substantiate the efficacy of surfactant treatment in term and near term CDH infants. Using the CDH Study Group Registry, investigators identified 448 neonates with isolated CDH who were $\geq$35 weeks' gestation and who were treated with ECMO within the first 7 days of life. One hundred fourteen infants received surfactant treatment while 334 infants did not. Surfactant replacement did not provide significant benefit in the infants' clinical course with respect to survival, length of intubation, or subsequent need for supplemental oxygen.[13] In an autopsy study comparing ipsilateral lung samples from 16 preterm fetuses with CDH to age-matched controls who died of nonpulmonary disease, no differences were found in surfactant protein or phospholipid concentrations.[9]

The optimal timing for ECMO support in patients with CDH remains controversial. It has been used preoperatively in unstable patients or post-CDH repair if pulmonary hypertension supervenes. Repair of the hernia can be accomplished, while the patient is on bypass support if necessary, although in this circumstance bleeding complications are higher because the patient is anticoagulated.

Autopsy studies of CDH lungs confirm diminished lung volumes and show evidence of severe barotrauma often when ventilator exposure was relatively short. Wung and associates had previously established the efficacy of avoiding hyperventilation in infants with PPHN.[69] Based on this experience, investigators at Morgan Stanley Children's Hospital of New York Presbyterian first applied the technique of gentle ventilation to patients with CDH in the hope of avoiding barotrauma and preserving the integrity of the vulnerable hypoplastic lungs. Permissive hypercapnia, rather than hyperventilation, was the goal of this strategy, using low respiratory pressures (usually $\leq$25 cm H_2O) to achieve adequate chest rise rather than a target CO_2. Preductal saturations greater than 90% are the goals in oxygenation, but oxygen saturations between 80% and 89% are tolerated if the patient is otherwise stable. High-frequency oscillatory ventilation (HFOV) is used when the patient's preductal oxygen saturation is less than 80 or the $P\text{CO}_2$ persistently > 65 torr. Postductal saturations are often lower. ECMO is used to support infants with isolated CDH whose condition cannot be stabilized with gentle ventilation.

Using this approach, Boloker and colleagues reported 76% (91 of 120) survival in a cohort of 120 consecutive infants with CDH treated with delayed surgery and gentle ventilation.[8] Excluding 18 infants who were not offered surgery (lethal anomalies, overwhelming pulmonary hypoplasia, neurologic complications), 84% survived to discharge. ECMO was used in only 13.3% of infants.

Wilson and associates previously reported no significant improvement in CDH survival with the adoption of delayed surgery or ECMO at Boston Children's Hospital.[68] They subsequently adopted a treatment protocol emphasizing permissive hypercapnea, control of pulmonary hypertension, and judicious support of cardiac function. Using this strategy, 36 of 39 (93%) consecutive infants survived to discharge. Of particular interest was the survival in 8 of 10 (80%) infants with structural heart defects. Previously few infants with serious congenital heart lesions and CDH had survived at Boston Children's Hospital or elsewhere.

In fact, the true impact of ECMO on CDH survival remains unproved. Many small studies report improved survival with ECMO use, but these tend to use historical controls that tend to exaggerate treatment effect. The same is true for high-frequency ventilation studies in CDH. Of all therapeutic interventions used in the treatment of patients with CDH and hypoxic respiratory failure (HRF), only iNO has been studied in a prospective, randomized trial. Disappointingly, neither the mortality rate nor the need for ECMO was diminished in those infants receiving iNO in two studies involving 83 patients.[11,19]

FAILURE OF MAXIMAL MEDICAL THERAPY

Because ECMO is an invasive procedure, it is currently reserved for infants receiving optimal conventional therapy who meet criteria indicating a 60% to 80% or greater chance of dying. It is critical that these infants be identified quickly so that adjunctive therapies, such as surfactant, HFOV, and iNO can be used to stabilize, and hopefully reverse, respiratory failure short of ECMO. For infants whose respiratory status cannot be stabilized, however, ECMO should be initiated without delay, certainly before the infant is moribund.

The nature of maximal conventional therapy for respiratory failure in the newborn varies considerably among tertiary care units around the world and remains the source of much debate and controversy. No randomized trials have addressed the efficacy of several modalities employed in the treatment of neonatal respiratory failure complicated by PPHN.[67] These included muscle paralysis, hyperventilation to induce respiratory alkalosis, alkali therapy to promote metabolic alkalosis, and vasodilator therapy, including tolazoline (no longer commercially available), prostaglandins E and D, nitroprusside, and magnesium sulfate. The use of the aforementioned vasodilators has been limited by their unpredictable side effect of systemic hypotension.

Using high-frequency ventilation with the aim of decreasing ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch and improving oxygenation has been successful in some series.[10] Surfactant use has also been shown to decrease the need for ECMO in newborns with parenchymal disease (e.g., RDS, pneumonia, meconium aspiration) and respiratory failure.[45] Inhaled NO is a pulmonary vasodilator that selectively lowers pulmonary vascular resistance without adversely affecting systemic blood pressure. In prospective randomized trials of iNO in newborns with PPHN (including CDH), iNO improved oxygenation in most infants and decreased the need for ECMO by 40%.[20]

ECMO Referral

One of the hardest decisions faced by neonatologists in tertiary care is when to refer a newborn in respiratory failure to an ECMO center. Because of the volatile nature of PPHN, the risk of sudden cardiorespiratory decompensation and death remains high in any infant not responding favorably to conventional supportive measures. Likewise, transporting these unstable babies is problematic, with one series reporting a 25% mortality among ECMO transports.[7] In another study, the use of iNO during transport improved oxygenation in a cohort of 25 high-risk neonates with unstable cardiopulmonary disease. All 25 infants survived transport, many over long distances.[40]

It is essential that ECMO referrals be made as expeditiously as possible, certainly before the infant is moribund and preferably before the baby reaches ECMO-eligible respiratory criteria. Early and frequent telephone contact with an ECMO physician to discuss the details of each case can help establish transport criteria agreeable to both parties.

The parameters most often used to predict poor outcome in infants failing conventional or high-frequency ventilator support and regarded as entry criteria for ECMO are listed in Box 44-15. These criteria are applied when the infant has reached optimal ventilatory support on 100% oxygen.

One criterion is the oxygenation index (OI):

$$\mathrm{OI} = \frac{\text{mean airway pressure} \times \mathrm{FiO_2} \times 100}{\text{Postductal } \mathrm{PaO_2}}$$

This equation has a certain appeal in that it reflects the ventilator support being used to achieve any given $\mathrm{PaO_2}$. The oxygenation index is the parameter used in most ECMO centers today to gauge the severity of respiratory insufficiency.

Another criterion is the alveolar-arterial oxygen gradient ($\mathrm{AaDO_2}$):

$$\mathrm{AaDO_2} = \mathrm{FiO_2}(\mathrm{P} - 47) - \mathrm{PaO_2} - \mathrm{PaCO_2}\left[\mathrm{FiO_2} + \frac{(1 - \mathrm{FiO_2})}{\mathrm{R}}\right]$$

where P is the barometric pressure, 47 is the partial pressure of water vapor, R is the respiratory quotient (0.8), $\mathrm{FiO_2}$ is the fractional inspired oxygen concentration, $\mathrm{PaO_2}$ is the partial pressure of arterial oxygen, and $\mathrm{PaCO_2}$ is the partial pressure of arterial carbon dioxide. When $\mathrm{FiO_2}$ is 100% and assuming $\mathrm{PAO_2}$ (partial pressure of alveolar oxygen) is equivalent to $\mathrm{PaO_2}$, the equation reduces to

$$\mathrm{AaDO_2} = \mathrm{P} - 47 - \mathrm{PaO_2} - \mathrm{PaCO_2}$$

where P is 760 mm Hg at sea level.

An OI of ≥ 40 or an $\mathrm{AaDO_2}$ gradient of ≥ 620 serve as baseline criteria for ECMO eligibility. Assessment of respiratory failure parameters begins after infants have received surfactant or iNO, or both, when clinically relevant. Supporting cardiac output with judicious use of volume loading and pressor infusion is key to maintaining adequate oxygen delivery in newborns with borderline blood pressure and respiratory insufficiency. In the ventilatory management of these infants equal attention must be paid to providing optimal ventilation without overdistending the lung, which compromises venous return and hence adversely affects cardiac output. Hyperventilation (to induce respiratory alkalosis) is no longer recommended in the ventilatory management of PPHN.

BOX 44–15 Formulas and Criteria for Neonatal Extracorporeal Membrane Oxygenation

OXYGENATION INDEX (OI)

$\mathrm{OI} = (\mathrm{MAP} \times \mathrm{FiO_2} \times 100)/\mathrm{PaO_2}$

Usual criterion is OI of 35 to 60 for 0.5 to 6 hours.

ALVEOLAR-ARTERIAL OXYGEN ($\mathrm{AaDO_2}$) GRADIENT

$\mathrm{AaDO_2} = \mathrm{FiO_2}\,(\mathrm{P} - 47) - \mathrm{PaO_2} - \mathrm{PaCO_2}\,[\mathrm{FiO_2} + (1 - \mathrm{FiO_2})/\mathrm{R}]$

Usual criterion is $\mathrm{AaDO_2} > 605\text{-}620$ mm Hg (at sea level) for 4 to 12 hours.

PARTIAL PRESSURE OF ARTERIAL OXYGEN

Usual criterion is $\mathrm{PaO_2} < 40$ mm Hg for 2 hours.

ACIDOSIS AND SHOCK

Usual criterion is $\mathrm{pH} < 7.25$ for longer than 2 hours or with hypotension.

From Van Meurs KP, et al: ECMO for neonatal respiratory failure. In: Van Meurs L, et al, editors: *ECMO: extracorporeal cardiopulmonary support in critical care*, 3rd ed, Ann Arbor, MI, 2005, ELSO, pp 273-296.

For the infant who remains severely hypoxic and hypotensive despite every supportive measure offered the choice for ECMO is easily made. However, for the infant whose blood gases and systemic blood pressure are marginally stable on maximal support including iNO, but who is unable to wean from these supports, the choice between invasive bypass support (ECMO) and the risk for extended volutrauma to the lungs remains difficult.

One large study in newborns with respiratory failure and PPHN confirmed that aggressive weaning of iNO over 96 hours can be accomplished without increasing the risk for ECMO.[11] Judicious but steady weaning of both $\mathrm{FiO_2}$ and ventilator settings is recommended to avoid serious lung injury. If the infant's respiratory status fails to stabilize and improve over a number of days, then ECMO is an alternative.

ECMO Follow-up

More than 23,000 infants have been treated for respiratory failure in more than 100 ECMO centers worldwide for an overall survival of 76%.[17] The outcome of these children compares favorably with that of term and near-term infants surviving severe respiratory compromise and PPHN with conventional management.

A valid criticism of early ECMO follow-up studies was the lack of proper control data, that is, the outcome of infants with severe respiratory compromise who were managed during the ECMO era with conventional treatment alone. Such control data are essential for distinguishing morbid outcome caused by the underlying disease process and NICU management of respiratory failure, or both, from the morbidity that is secondary to the ECMO procedure itself.

To address this issue, Walsh-Sukys and associates were the first to report on the neurodevelopmental outcome of 74 consecutive neonates older than 34 weeks' gestation admitted to Rainbow Babies and Children's Hospital with severe respiratory failure.[66] Eighteen of 24 (75%) infants treated conventionally survived, whereas 43 of 48 (90%) treated with ECMO survived. Patients were evaluated at 8 and 20 months. Sixty-two of 72 (91%) survivors were seen in follow-up. Four of 17 (24%) conventionally treated survivors, and 10 of 38 (26%) ECMO-treated survivors had neurodevelopmental impairment defined as either Mental Developmental Index Score lower than 80 or neurosensory impairment. The conventionally treated group had significantly more chronic lung disease, longer duration of oxygen therapy, more chronic reactive airway disease, and more rehospitalizations than those treated with ECMO. Macrocephaly was noted in 24% of ECMO survivors, all treated with VA bypass, but in none of the conventional group. This study concluded that ECMO survivors did not suffer increased neurologic morbidity compared with similarly ill neonates managed conventionally and they may have fewer pulmonary sequelae.

Vaucher and colleagues prospectively assessed growth and neurodevelopmental outcome in a cohort of 190 infants surviving neonatal respiratory failure who met institutional criteria for the use of ECMO.[64] Fifty-two were managed with conventional or high-frequency ventilation, and 138 required ECMO. At 12 to 30 months of age the mean developmental scores of ECMO survivors were similar to those for infants who survived without ECMO. Neuroimaging abnormalities or diagnosis of bronchopulmonary dysplasia each independently predicted adverse neurodevelopmental outcome regardless of treatment strategies used in the NICU. This observation mirrors the same predictors of poor outcome described in another high-risk cohort familiar to neonatologists, namely, infants with very low birthweight (less than 1000 g).

In 2006, the UK Collaborative ECMO Trial Group published the 7-year follow-up of their surviving patients from the largest prospective randomized ECMO trial carried out so far.[47] In this study, a single psychologist assessed 90 of the 100 children available for follow-up without prior knowledge of treatment allocation (ECMO versus conventional management). At age 7 years, there was no difference in cognitive function between the 56 patients randomized to ECMO versus the 34 controls; 68 (76%) children recorded a cognitive level within the normal range. Learning problems were similar in the two groups. There were notable difficulties with spatial and processing tasks; the children also had particular difficulty completing tasks of reading comprehension with 35 (39%) scoring below the 10th percentile. There was no difference in laterality of neuromotor disability between the two groups. A higher respiratory morbidity and increased risk of behavioral problems among children treated conventionally (first reported in the 4-year follow-up) persisted. In the conventionally treated group, 11 (32%) of 30 children continued to have wheezing attacks and 14 (41%) of 32 regularly used an inhaler over the 12 months before study assessment. These compared with 6 (11%) of 43 ECMO children who wheezed and 14 of 48 (25%) using an inhaler. In behavioral assessment, the total deviant score was higher in the conventionally treated group—38% versus 18% in ECMO survivors. The most commonly described difficulty reported by parents and teachers in both groups was hyperactivity; overall, 22 of 85 (26%) children had difficulty with hyperactivity.

The primary outcome of known death or severe disability occurred in 37% of the ECMO group compared with 59% in the conventional group (relative risk 0.64; $P = .004$) leading the authors to reaffirm that ECMO remains a beneficial treatment. These results, which have not changed from the 4-year follow-up, are equivalent to one additional child surviving without severe disability for every four to five children referred for ECMO.

Overall, 31 of 56 (55%) ECMO survivors and 17 of 34 (50%) conventionally treated survivors were assessed with no disability at 7 years. The authors concluded that the data collected at 1, 4, and now 7 years' follow-up of the UK ECMO Trial participants suggest that the underlying disease process (and associated physiologic instability) appears to be the major influence in long-term outcome. Their findings confirm significant long-term morbidity in many surviving children who had life-threatening respiratory failure soon after birth, regardless of their subsequent medical treatment. Furthermore, while both groups had problems, the beneficial influence of ECMO persists to 7 years. Clearly, newborns presenting with PPHN and severe respiratory failure require ongoing developmental assessment well beyond their NICU experience, and whether or not they required ECMO support.

Cost Analysis

ECMO saves lives, but it does cost more than conventional management of neonatal respiratory failure. A cost-effectiveness analysis of neonatal ECMO was published based on 7-year results from the UK Collaborative ECMO Trial.[55] Mean health service costs during the first 7 years of life were £30,270 in the ECMO group compared with o £10,229 in the conventional management group. Data for this analysis included air and ground transport costs, initial and all subsequent hospitalizations, outpatient hospital care, and community health care, as well as other health care services. These combined costs over 7 years translated into a cost of £13,385 per life-year gained. The incremental cost per disability-free life-year gained was estimated at £23,566. These incremental costs should decrease as the surviving children grow older. The authors concluded that ECMO was not only clinically effective, but also as cost-effective as other intensive care technologies in common use.

Alternative Uses for ECMO

ECMO support has been extended to a broader array of high-risk candidates. A small number (5%) of infants undergoing surgical repair of their heart defects cannot be successfully weaned from cardiopulmonary bypass (CPB) or they develop low cardiac output syndrome several hours after repair.[31] VA ECMO can provide circulatory support for these patients until their cardiac function improves. However, survival in postcardiotomy infants requiring ECMO is low (38%) compared with respiratory case survival (76%).[17]

In a single center retrospective study of 671 patients undergoing open heart surgery between January 2001 and October 2003, 36 (5.4%) infants received extracorporeal life support within one day after surgery (age younger than 30 days, n = 34). Overall, 28 patients (78%) were weaned from extracorporeal support successfully, and 24 (67%) survived to hospital discharge. These infants had a variety of disorders including single ventricle anatomy as well as failed hemodynamics postcardiotomy. The authors concluded that expanded use of extracorporeal support may improve outcome in some of the highest risk neonates, especially those with univentricular anatomy.[3] In another single center review from Vanderbilt University Medical Center, 84 children with congenital heart disease required postcardiotomy ECMO between January 2001 and September 2004. The median age of the patients was 128 days (1 day to 5 years), and median weight was 4.5 kg (2 to 18 kg). Fifty-two (61.9%) survived for more than 24 hours after decannulation, but only 31 (36.9%) survived to discharge. High arterial lactate levels at the time of ECMO initiation were strongly correlated with poor outcome. Inability to wean off ECMO by 6 days correlated with high mortality.[59]

ECMO has been used as a bridge to cardiac transplantation in infants with myocarditis or complex congenital heart disease, as well as support for early graft failure following heart transplantation in infancy. ECMO has also been used to stabilize infants with refractory supraventricular tachycardia until antiarrhythmic drugs could be maximized or radioablation of the aberrant pathway accomplished.[65] Tracheal reconstruction in infants with serious congenital defects of the upper airway has also been successfully accomplished while on ECMO.[30]

ECMO Present and Future

ECMO has become an established treatment for cases of hypoxic respiratory failure refractory to conventional management. Because of advances in neonatal respiratory care, the number of annual neonatal respiratory ECMO cases has declined from a peak of 1418 in 1992 to 800 infants in 2007.[17] Surfactant treatment, gentle ventilation, permissive hypercapnea, high-frequency ventilation, and inhaled nitric oxide have all contributed to the welcomed decline in the need for ECMO rescue in neonatal respiratory failure.

Research efforts continue to focus on PPHN treatment that could preclude the need for bypass altogether. Randomized, controlled trials over the past decade have proven the efficacy of iNO as the selective pulmonary vasodilator that decreases the need for ECMO (see later). Other drugs used extensively in the treatment of adult and pediatric idiopathic pulmonary hypertension have been reported, so far in small case series only, to hold promise in the treatment of PPHN. As the number of neonatal pulmonary cases declines, the use of ECMO support for cardiac low-output syndrome, as in myocarditis or postcardiotomy has increased. Time is needed to determine whether this use of extracorporeal support will translate into increased survival or improve neurodevelopmental outcome in this high-risk cohort.

NITRIC OXIDE THERAPY

PPHN is a serious and sometimes lethal cardiorespiratory complication of the transition to extrauterine life. The incidence ranges from 0.43 to 6.8 per 1000 live births.[67] It is well recognized that in the absence of congenital malformations of the lung, this condition improves if the patient can be supported through the period when pulmonary vascular resistance is most volatile, often exceeding systemic vascular resistance. Support is required for a matter of only days, usually less than 2 weeks.

Potent vasodilators such as tolazoline, nitroprusside, prostaglandin E_1 (PGE_1), and prostaglandin D (PGD) have been shown in small trials to reverse the severe pulmonary vasoconstriction that causes profound hypoxemia in PPHN. Although all these medications are efficacious in lowering pulmonary vascular resistance, their use is severely limited by a lack of pulmonary selectivity. Systemic vasodilation invariably occurs, leading to hypotension, compromised tissue perfusion, and inadequate oxygen delivery to vital organs.

In 1980, Furchgott and associates described an endogenous vasodilator called *endothelium-derived relaxing factor* (EDRF).[21] In 1987, NO was identified as the molecule responsible for the biologic activity of EDRF.[35] Previously recognized as a toxic component in cigarette smoke and atmospheric pollution, NO has proven to be an important endogenous mediator of multiple physiologic processes in the human body, including regulation of vascular tone. When delivered by inhalation, NO can decrease pulmonary vascular resistance and improve pulmonary bloodflow without compromising systemic blood pressure or worsening $\dot{V}/\dot{Q}$ mismatch. At present, NO is the most selective pulmonary vasodilator available for clinical use.

Physiology and Pharmacology

NO is a short-lived, highly reactive molecule, cleaved from its precursor, arginine, by the enzyme nitric oxide synthase (NOS). NOS has been classified into two forms. The constitutive enzyme is found in endothelium, neurons, platelets, the adrenal medulla, and the macula densa of the kidney. The inducible form is generated under pathologic conditions by macrophages, hepatocytes, and airway epithelial and smooth muscle cells. NOS converts arginine to citrulline, and NO, as follows:

$$\text{Arginine} \xrightarrow{\text{NOS}} \text{Citrulline} + \text{NO}$$

Pulmonary endothelial cells are an active site of NOS activity in both fetal and newborn lung. NO generated in the endothelium enters the adjacent vascular smooth muscle where it binds to soluble guanylate cyclase. This induces a conformational change and upregulation of this enzyme, promoting synthesis of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) (Fig. 44-88). Activation of a cascade of GMP-dependent protein kinases results in calcium efflux from the cells, resulting in smooth muscle relaxation and hence pulmonary vasodilation. Intracellular cGMP is therefore a key modulator of vascular smooth muscle tone. Its biologic half-life is short, however; a family of phosphodiesterases hydrolyze and inactivate cGMP and help regulate the concentration

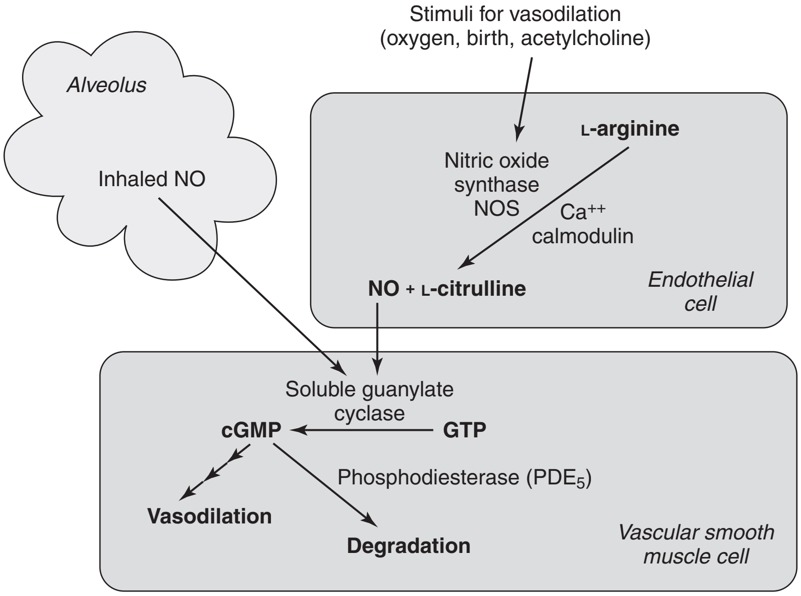

Figure 44–88. Nitric oxide (NO) is produced in the vascular endothelium during the conversion of L-arginine to L-citrulline by the enzyme NO synthase (NOS). Endogenous NO from the endothelium or exogenous NO inhaled into the alveolus diffuses to the vascular smooth muscle cell, stimulating soluble guanylate cyclase, which increases cyclic guanosine monophosphate (cGMP) production. Phosphodiesterase, specifically PDE5, hydrolyzes cGMP, reversing smooth muscle relaxation. GTP, guanosine triphosphate.

and duration of action of cGMP within the smooth muscle cell.

Lung endothelial NOS mRNA and protein are present in the early fetus and increase with advancing gestation in utero in the rat model. In the fetal lamb, intrapulmonary infusion of NOS inhibitors increases basal pulmonary vascular resistance by 35% as early as the second trimester.[1] Endogenous NO plays a pivotal role in the acute decrease in pulmonary vascular resistance at birth along with other vasodilators such as adenosine and prostacyclin. NOS expression is largely responsible for postnatal adaptation of the lung circulation following delivery. Nitrovasodilators, such as sodium nitroprusside, nitroglycerin, and the organic nitrates, donate NO through the NO cGMP pathway to promote vasodilation. When administered by inhalation NO rapidly diffuses across the alveolar membrane to relax the pulmonary vascular bed through upregulation of cGMP production. In contrast with intravenous vasodilators, inhaled NO has minimal effect on systemic vascular tone because of rapid binding and deactivation by reduced hemoglobin within the pulmonary vascular bed.

Nitric Oxide Toxicity

Clinicians should be aware of toxicity issues when using inhaled nitric oxide (iNO) in human subjects. Nitric oxide reacts with oxygen to form nitrogen dioxide (NO_2). Both NO and NO_2 are toxic, causing death in dogs at concentrations between 0.1% and 2% due to methemoglobinemia and pulmonary edema.[20] This concentration is much higher than the inhaled dose of NO used therapeutically in newborns (1 to 80 ppm) or the endogenous levels of NO produced in the endothelium (ppb). When NO reacts with superoxide in the lungs peroxynitrite is formed, which can result in membrane lipid peroxidation. Furthermore, at levels used in clinical trials, NO can inhibit platelet aggregation and adhesion. In one study, prolonged bleeding time was noted in healthy adults breathing 30 ppm iNO. However, no studies to date have reported issues of systemic bleeding with iNO treatment. Occupational safety guidelines limit exposure to NO in the workplace to 8 hours a day at levels of 25 ppm, while 3 ppm is the upper limit for NO_2.[20] Patients treated with iNO must have methemoglobin levels monitored to ensure that levels do not exceed 5% to 7%. This is rarely a problem in neonates treated with 20 ppm or lower.

Neonatal Studies of Inhaled Nitric Oxide

TERM INFANTS

iNO has emerged as the best-studied pulmonary vasodilator in human neonates with hypoxic respiratory failure and PPHN. To date, 14 prospective, randomized trials have been published on the use of iNO in term or near-term infants with severe respiratory failure. The largest of these was the NINOS trial sponsored by the National Institute of Child Health and Human Development, in which 235 infants older than 34 weeks' gestation who had a diagnosis of hypoxic respiratory failure were randomized to iNO at 20 to 80 ppm in 91% to 96% FiO_2 versus standard ventilator management with 100% oxygen. The primary endpoint of this trial was death or ECMO. Although the mortality rate was no different in either treatment arm, there was a 40% reduction in need for ECMO among the babies treated with inhaled NO: 54% of infants required ECMO in the control arm, 39% required ECMO in the iNO treatment arm.[54] Follow-up of survivors at 2 years showed no difference in neurodevelopmental outcome between treated and control patients.[53]

In Kinsella and colleagues' study, 205 infants with PPHN were randomized to iNO and conventional ventilation or to HFOV alone.[39] Failure to respond to either treatment scheme led to crossover to the alternate study arm, and failing this, the infants received iNO plus HFOV. Treatment with HFOV and iNO proved more successful than either treatment alone in newborns with severe PPHN.

In another large multicenter trial of iNO in newborns, Clark and coworkers reported a 38% reduction in ECMO use and no difference in mortality among 248 infants with PPHN randomized to low-dose, short-duration (96 hours) iNO treatment versus control.[11] This study, unlike previous trials, showed a significant decrease in chronic lung disease in infants treated with iNO.

A meta-analysis of the results from 14 randomized trials (including the three studies detailed earlier) of iNO use in newborns with PPHN demonstrated that 50% of hypoxic near-term and term infants responded to iNO within 30 to 60 minutes.[20] The PaO_2 in the patients treated with iNO was 53 mm Hg higher (weighted mean difference) than in controls, and the OI was 15 units lower than in control patients. Mortality was not reduced in any study of iNO, perhaps because ECMO was used as a rescue therapy in nonresponders in whom severe hypoxic respiratory failure persisted.

As mentioned earlier in this section, iNO was found to be of no acute benefit in newborns with CDH. In a prospective, randomized trial of 52 infants with CDH, randomized separately in the NINOS trial, iNO neither reduced mortality nor decreased the need for ECMO. In fact, the need for ECMO was higher in the infants treated with iNO in this trial.[19] Most infants with CDH do have transient improvement in oxygenation when treated with iNO, but this response is not sustained. This observation exemplifies the importance of choosing clinically robust endpoints when testing a new drug for clinical efficacy rather than a target physiologic response (such as Po_2) which may not be sustained long enough to alter clinical outcome.

In contrast, Kinsella's group reported inhaled NO to be useful in treating a subset of older CDH patients, after surgical repair, whose pulmonary hypertension, by echocardiographic measurements, remained severe at the time of elective extubation (26 ± 3 days). Although their respiratory status was much improved (OI average 4 ± 1) after surgical repair, 10 of 47 CDH infants were found to have protracted pulmonary hypertension and were successfully treated with iNO administered through nasal cannulae until subsystemic pulmonary artery pressures were achieved. The infants received iNO in this fashion for a median of 17 days (range 5 to 60 days).[41]

The toxicity of NO and its metabolites in the newborn lung bears careful monitoring, particularly with regard to long-term exposure. The incidence of chronic lung disease is not higher in infants treated with iNO compared to untreated controls with similar disease severity. On the contrary, a prospective randomized study of low dose (5 ppm) iNO treatment in newborns greater than 34 week's gestation with PPHN reported a substantial reduction in the rate of BPD among survivors treated with iNO.[11] Despite its known antiplatelet activity, there have been no increased bleeding complications reported among preterm neonates treated with NO in randomized clinical trials.

On the evidence available, including the neurodevelopmental and general medical outcome information, near-term and term infants with hypoxic respiratory failure unresponsive to oxygen and ventilator support, excluding infants with CDH, should have a trial of iNO. This therapy significantly reduces the need for ECMO with the number needed to treat (NNT) of 5.3.[20] Therapy should be confined to infants who are severely ill with an OI greater than 25. Starting treatment earlier does not further reduce mortality or the need for ECMO.[43]

PREMATURE INFANTS

In preterm infants, survival and outcome are limited by respiratory distress syndrome (RDS) and its sequela, bronchopulmonary dysplasia (BPD). There are many potential short-term and long-term benefits of iNO in preterm newborns (Box 44-16). However, the use of iNO in this high-risk cohort was approached with trepidation because of the increased risk of intracranial hemorrhage and NO's known antiplatelet effect. Early pilot trials confirmed acute improvement in oxygenation in preterm (less than 1500 g) infants with severe hypoxic respiratory failure treated with iNO. However, survival was not improved, and the rate of intracranial bleeding was alarmingly high.

Several large randomized trials of iNO use in preterms have now been completed where the primary outcome focuses on survival without BPD. In a single center trial, Schreiber and colleagues randomized 207 infants with low birthweight (less than 1500 g) to treatment with a 7-day course of iNO or placebo starting on the first day of life. The authors reported a 24% reduction in the incidence of BPD and death in the iNO groups, largely accrued in the subset of infants with milder respiratory failure (OI <6.94). A 47% decrease in severe intracranial hemorrhage (ICH) and periventricular leukomalacia (PVL) was also noted.[57] At 2-year follow-up, 24% of the iNO-treated patients had abnormal neurodevelopment compared with 46% of the control group (NNT=5).[49]

Van Meurs and colleagues enrolled 420 newborns (401 to 1500 g birthweight) in a multicenter randomized, controlled trial through the NICHD.[63] Only responders (i.e., infants showing improved PaO_2) continued on inhaled NO; the average treatment duration was 76 hours. They found no difference in the incidence of death or BPD at 36 weeks' postmenstrual age between the iNO and control groups. Post hoc analysis revealed that NO reduced these rates in neonates weighing more than 1000 g, however. A higher rate of ICH and PVL noted in the infants weighing less than 1000 g (43% iNO versus 33% control) was concerning. An editorial accompanying this manuscript pointed out that Van Meurs and colleagues' patients were smaller, more immature, and had more severe respiratory

BOX 44–16 Potential Benefits of Inhaled Nitric Oxide in Preterm Infants

SHORT-TERM

Selective pulmonary vasodilation
Improvement in $\dot{V}/\dot{Q}$ matching
Decreased neutrophil accumulation and activation
Improvement in oxygenation and hypoxic respiratory failure

LONG-TERM

Reduced need for oxygen and decrease in oxidant stress
Improved surfactant function
Decreased airway resistance
Improved lung growth due to stimulation of angiogenesis and alveolarization

---

From Arul N, Konduri GG: Inhaled nitric oxide for preterm neonates, *Clin Perinatol* 36:43, 2009.

failure at study entry compared with Schreiber's study, making comparisons between the two trials problematic.

In 2006, two large prospective, randomized trials of iNO in preterm babies were published. Kinsella and colleagues randomized 793 newborns, less than 34 weeks' gestation, within 48 hours of birth, to 5 ppm iNO versus placebo gas for 21 days or until extubation. OI at study entry was 5.4 to 5.8. There was no difference in the incidence of death or BPD between groups. However, iNO reduced the incidence of BPD by 50% for infants with birthweights greater than 1000 g ($P = .001$, NNT 3). Low-dose iNO reduced the combined incidence of intracranial hemorrhage, PVL, and ventriculomegaly for the entire study population receiving iNO ($P = .032$, NNT 16).[42]

Ballard and colleagues, also in 2006, reported on the outcome of their prospective, randomized, controlled and masked trial of iNO treatment of preterm infants.[4] Five hundred eighty-two infants who required ventilatory support between 7 and 21 days of age were randomized (birthweight 500 to 1250 g). Infants were enrolled in the study with an estimated OI between 5 and 9; treatment with iNO versus study gas lasted a minimum of 24 days. The incidence of survival without BPD was increased in the iNO treatment group (43.9%) compared with controls (36.8%, $P = .04$, NNT 14). This effect was largely noted in those treated between 7 and 14 days of life, suggesting that early treatment is important to prevent BPD. One-year follow-up of study survivors was notable for decreased pulmonary sequelae reflected in decreased medication requirement in the iNO cohort.[29]

Recently, a large multicenter masked, placebo-controlled trial of inhaled nitric oxide (iNO) for the prevention of bronchopulmonary dysplasia (BPD) in preterm infants was published. Eight hundred infants between 24 and 28 6⁄7 weeks' gestation were randomized from 36 centers in 9 countries in the European Union. Infants were enrolled within 24 hours of birth and received either low-dose iNO (5 ppm) or placebo (nitrogen gas) for 7 to 21 days. In this industry-sponsored study, neither survival nor the incidence of BPD at 36 weeks' postmenstrual age was improved with iNO treatment.[48]

In summary, the available evidence from randomized trials detailed in this section suggests that low-dose iNO may be safe and effective in reducing the risk of death or BPD for the subset of preterm infants weighing more than 1000 g at birth. A neuroprotective effect was present in some, but not all, treated patients. This effect was larger in infants with lower disease severity at study entry. The apparent lack of efficacy in the tiniest, most immature preterm infants is disappointing, especially in light of animal data, which suggest that NO plays a key role in lung morphogenesis.[2]

Alternative Treatments and Avenues for Future Research

Future clinical trials of nitric oxide will better define the neonatal patient population for whom this inhalational treatment is efficacious. The optimum dose and duration of therapy require further refinement. For the 30% to 40% of near-term and term newborns with PPHN who fail to respond to iNO, or who do not sustain improvement in oxygenation, other drugs are available for study. Particularly in countries with limited medical resources, alternative treatment to costly iNO or ECMO would be most welcome.

A different, but related, approach to the treatment of PPHN would be to augment endogenous vasodilator therapy by inhibiting the rapid degradation of cyclic nucleotide second messengers, cGMP and cAMP, which play a central role in modulating smooth muscle relaxation in the pulmonary vascular bed. Phosphodiesterases (PDEs) have a wide distribution in normal mammalian tissues. They are divided into 11 distinct families based on substrate specificity and sensitivity. PDE5 inhibitors block the degradation of cyclic GMP (NO pathway) and PDE3 blocks the degradation of cyclic AMP (prostacycline pathway), both of which potentiate vasodilation.

Sildenafil is a specific PD5 inhibitor used primarily to treat erectile dysfunction. A number of small case studies have explored the therapeutic potential of sildenafil in treating PPHN because the lung is particularly rich in PDE5. In a double-blind, randomized, placebo-controlled study in 278 adults with primary pulmonary hypertension, sildenafil reduced mean pulmonary artery pressure and improved functional class of disease severity over 12 weeks of treatment. Sustained improvement over 1 year of treatment with sildenafil in adults with pulmonary arterial hypertension (PAH) was also confirmed, leading to Food and Drug Administration (FDA) approval for this drug in adults with PAH. However, safety and efficacy of sildenafil in the treatment of newborns with PPHN has not yet been established. In one small study, 13 patients were randomized to sildenafil treatment ($n = 7$) or placebo ($n = 6$). HFOV, iNO, and ECMO were not available in this center. The study was terminated early due to the deaths of six patients enrolled, five of whom were in the control arm.[5] Large randomized studies investigating the role of sildenafil as a single treatment agent, or in combination with iNO, for refractory PPHN have yet to be done.

A study on the kinetics of intravenous sildenafil in 36 infants with PPHN has been published.[52] Affected infants were treated within 72 hours of birth for a mean duration of 77 hours. Sildenafil clearance increased rapidly over the first 7 days of life, presumably due to increased hepatic clearance. Adverse side effects were mild to moderate in severity, and included hypotension (three subjects), labile blood pressure (one subject), and PDA (one subject). These data will pave the way for future clinical trials of this drug in newborns who are particularly sensitive to systemic vasodilation and $\dot{V}/\dot{Q}$ mismatch. The use of this potent vasodilating agent should be limited to prospective randomized trials until more information on the drug's safety and efficacy in the neonate becomes available.

Prostacyclin (Flolan; epoprestenol sodium), which affects pulmonary relaxation through upregulation of cyclic AMP levels, has emerged as one of the primary treatments of idiopathic pulmonary hypertension in adults and children where the drug is given by continuous intravenous infusion in nanogram doses.[33,46] Randomized trials of prostacyclin in PPHN have not been done. This drug has been used in small case series for the treatment of pulmonary hypertension in infants beyond the newborn period, however, with some success. Milrinone, a PD3 inhibitor, is widely used in intensive care as an inotrope and afterload-reducing agent. It has been described in case series to be useful in the treatment of pulmonary hypertension, particularly in the face of cardiac dysfunction. In the laboratory, milrinone enhances relaxation to prostacyclin and iloprost in pulmonary arteries isolated from a lamb model of PPHN.[44]

Iloprost, an aerosolized prostanoid, has been proven efficacious in adults with pulmonary hypertension, and has been successful in small case series in PPHN. Its drawback in adults is the requirement for aerosol treatments eight to 10 times per day. In the NICU, given the time frame of PPHN, this could be achievable. Blood pressure instability remains an issue with this as with any prostanoid; therefore, the use of iloprost should be confined to investigational pilot trials for the time being.[46]

Endothelin is a potent vasoconstrictor and a smooth muscle mitogen that may contribute to the development of PPHN. Increased endothelin levels have been measured in newborns with PPHN. Medications are available that block the endothelin receptors on vascular smooth muscle cells in the lung and ameliorate pulmonary vasoconstriction in adults with pulmonary hypertension. Bosentan is the most widely studied of these and is approved by the FDA for the treatment of pulmonary hypertension in adults. Bosentan improved cardiac index, and reduced mean PAP and PVR; functional class also improved in patients treated with bosentan. Liver toxicity, which appears to be dose dependent, is seen in 25% of bosentan-treated adults.[33,46] Whether this drug has any therapeutic efficacy in PPHN remains to be elucidated.

As with many new therapies, early reports of treatment response to NO were almost euphoric. Randomized, controlled trials have proven the efficacy of this inhaled vasodilator in PPHN, but they have also tempered our enthusiasm with the reality that up to 40% of term and near-term newborns with severe respiratory failure will not respond to iNO and still require ECMO support. For the preterm infant, the efficacy of iNO remains less certain. The lack of response in the more immature preterm infants (less than 1000 g birthweight) raises the question of whether these patients might require a longer course of iNO in order to enjoy the same benefits as their more mature counterparts with birthweights greater than 1000 g.

Lastly, the treatment of late-onset pulmonary hypertension in surviving infants with very low birthweight and BPD has emerged as a serious therapeutic challenge. Mortality in this cohort is high, and treatment with a variety of pulmonary vasodilators is being used with little evidence for which drug combinations are efficacious. A recent study of patients with BPD and pulmonary hypertension reported survival rates of 64% at 6 months and 52% at 2 years after the diagnosis of pulmonary hypertension.[38] Mourani and coworkers reported the effects of long-term sildenafil use for the treatment of pulmonary hypertension in infants younger than 2 years with chronic lung disease stemming from the neonatal period.[51] Eighteen of 25 were infants with low birthweight and BPD. The drug was judged to be well tolerated and effective in treated patients; median treatment duration was 241 days (range 28 to 950 days). However, 28% of treated patients also received other drugs for pulmonary vasodilation, including NO, calcium channel blockers, milrinone, and bosentan. Five of the 25 died during the 8-month follow-up period, emphasizing the vulnerability of this uniquely fragile cohort of NICU graduates.

Adjunctive therapies, as those discussed above, appear promising and may enhance the benefit of iNO, or replace this inhalational agent altogether. Within the relatively short period of neonatal intensive care, the discovery and use of one selective pulmonary vasodilator, such as iNO, represents a significant advance. Hopefully we can look forward to several treatment options for pulmonary hypertension once the therapeutic efficacy of these agents has been rigorously tested.

CHAPTER 45

The Cardiovascular System

The practice of the care of children with heart disease has increasingly become a neonatal specialty. Fetal diagnosis of congenital heart defects is now routine. Reparative cardiovascular surgery is commonplace in the first month of life and is now undertaken in utero. Defects once considered inoperable, most notably hypoplastic left heart syndrome, can be treated, with greatly improved long-term results. In parallel with these clinical advances, there has been exciting progress in understanding the cellular and molecular basis of normal and abnormal cardiogenesis and the relationship of heart defects to other congenital defects. The expansion in our understanding from combining clinical and basic science findings may lead to better predict the severity and consequences of congenital heart defects and also lead to strategies for alleviating the consequences to children and adults.

PART 1

Cardiac Embryology

Michiko Watanabe, Katherine S. Schaefer, Jamie Wikenheiser, Florence Rothenberg, and Ganga Karunamuni

The development of the heart has been a topic of study for hundreds of years. Nonetheless, many surprisingly basic questions have yet to be answered. For example, how does the cardiac pacemaking and conduction system develop, what factors allow the heart tube to bend in one direction and not the other, and how does the coronary vasculature develop in a stereotyped pattern? With the advent of new technologies and fields of study, these and other questions are being revisited, and answers are beginning to emerge. In combination with the traditional techniques, these new approaches have significantly advanced our understanding of normal and abnormal development.

Much of the current knowledge about cardiovascular development is based on studies of species other than humans, notably the chicken, quail, mouse, rabbit, fruit fly, and zebrafish. Remarkable similarities have been detected in molecular and cellular developmental mechanisms among these diverse species. Research on the developmental genetics of the fruit fly, for example, has made an impact on our basic understanding of genes important for vertebrate systems, including humans. In the other direction, information from clinics has been analyzed in detail in more easily accessible and manipulable systems such as the fruit fly, zebrafish, chicken, or mouse. The distance between the bedside and the bench is getting shorter.

The mature heart is the product of gene expression driven by endogenous and exogenous influences. The developing heart manifests its morphologic and physiologic plasticity under stress. A detailed understanding of the effects of the factors that drive normal cardiogenesis is necessary for understanding the causes and consequences of abnormal development. Errors in cardiac morphogenesis involved with septation, valve formation, and proper patterning of the great vessels are responsible for most forms of congenital heart disease. Normal heart development requires precise timing for coordination of the complex three-dimensional contortions of tissues, but paradoxically, these tissues also have a remarkable capacity for regulation that compensates for mistakes. This compensation can allow abnormal heart structures and functions to be compatible with life up to and even after birth, but complicates identification of primary and secondary cardiac anomalies.

It is possible to investigate cardiovascular development at various levels using a variety of disciplines: molecular biology, biochemistry, biomedical engineering, cell and tissue biology, genetics, physiology, and epidemiology. Significant results have emerged when information was shared across disciplines. For example, the hemizygous deletion in the elastin gene has been shown to be responsible for Williams syndrome (or Williams-Beuren syndrome), the autosomal dominant form of supravalvular aortic stenosis.[35] Predictions about the clinical manifestations of this disease were elucidated after mutant elastin proteins were found in humans; existence of these mutant proteins was proposed based on knowledge about the protein structure provided by studies at the bench. In the reverse direction, analysis of the mutant human proteins in animal models, in tissue cultures, and in in vitro studies advanced understanding of the disease and of the biochemistry and role of elastin in vascular cell signaling. The passage of information across these investigative levels has resulted in a remarkably productive synergy.

OVERVIEW OF NORMAL HEART DEVELOPMENT

The following description of human heart development, especially the earlier events, is synthesized from information provided by studies of animal models and human embryonic and fetal tissues. A timetable of selected events in human heart development is presented in Table 45-1.[29,32,40] Figure 45-1 is a diagram depicting the major transitions in early mammalian heart development.[43]

The primordia of the heart are identified as bilaterally symmetric heart fields derived from the lateral plate mesoderm. These primordia migrate through the primitive streak between the ectoderm and endoderm layers to become symmetric mesoderm regions on either side of the primitive streak. These tissues fuse cranially to form a tubular structure comprising an inner layer of endocardium, a thick layer of extracellular matrix, and an outer layer of myocardium. This simple tube begins to contract rhythmically and grows differentially so that dilations (primordia of the heart chambers) and constrictions (primordia of the partitions between chambers) appear along its length. Later additions to the distal ends of the tubular heart form the outflow tract (OFT) and the sinus venosus. Dextral looping of the tube brings the venous caudal portion to a more dorsal position and to the left of the arterial cranial portion as septation of the tubular heart begins. The epicardium arises from tissue dorsal to the heart at the level of the atrioventricular (AV) junction and spreads over the outer surface of the myocardium as a layer of squamous epithelial cells and associated connective tissue during the early phase of septation.

The atrial chamber, arising from expansion of a caudal region, divides into two chambers by the growth of a crescentic ridge from the anterodorsal wall at the narrowest point of the atrial chamber. This ridge grows and fuses with the dorsal and ventral endocardial cushions, which are themselves growing and fusing with each other. Before the atrial septum completely closes the ostium primum, perforations appear and coalesce in the dorsal portion of the septum to form a single opening: the ostium secundum, later termed the *foramen ovale*. A second atrial septum subsequently grows to the right of the primary atrial septum; in conjunction with the primary atrial septum, it forms a one-way valve (right-to-left blood flow only) between the two atria in the fetus. This avenue of blood flow is permanently closed shortly after birth to complete atrial septation.

Ventricular septation begins after the primary atrial septum is formed. The ventricular septum results from the growth and remodeling of trabecular sheets, continues with expansion of the ventricular chambers, and ends with the fusion of several tissues, including endocardial cushions and the muscular septum, to form the membranous and muscular interventricular septum. The OFT septation is the result of growth and fusion of spiraling ridges that eventually divide the truncus into aortic and pulmonary tracts. The venous and arterial vessels (aortic arches) undergo degeneration, fusion, and growth to attain the mature structures.

The human heart has completed the major morphogenetic processes 8 weeks after fertilization. What follows is the completion of maturation of structures, growth, accumulation of cellular junctions at the intercalated discs, biochemical adjustments, and compensation for the changes in patterns of blood flow after birth, such as permanent closure of the foramen ovale of the atrial septum and closure and fibrosis of the ductus arteriosus.

SCIENTIFIC BASIS OF CARDIOGENESIS

Precardiac to Cardiac Tissues: Commitment and Formation of Primary Axes

The tissue regions giving rise to the heart have been mapped by the application of dyes, particles, and radiolabels to stages when the vertebrate embryo comprises two layers: the epiblast (or ectoderm) and the endoderm. The process of gastrulation, the movement of precardiac epiblast cells through the primitive streak, appears to be important in specification. These early determinative events have been elucidated largely by studying fruit fly genetics and by manipulating amphibian and avian embryos.

Transcription factors are proteins that bind as complexes to specific DNA sequences and influence the expression of genes (Fig. 45-2).[8,12] Such factors influence many aspects of cardiogenesis[12] and include members of the following families: the helix-loop-helix proteins (dHand and eHand), zinc finger proteins (GATAs), homeobox gene proteins (NKX2.5), and MADS box proteins related to serum response factor. Of the zinc finger proteins, GATA4, 5, and 6 are much studied members of the evolutionarily conserved transcription factor subfamily that recognizes a "GATA" DNA sequence motif. These have been implicated in the early specification of embryonic tissue destined to become heart.

An example from the homeobox gene family demonstrates how the study of fruit flies has advanced our understanding of human heart development. The dorsal vessel pumps hemolymph (insect blood) and is considered the insect heart. It is derived from mesoderm under the influence of homeobox genes. The mutation of one of these genes, *tinman,* results in absence of the dorsal vessel. Frog and mouse homologues of these homeobox genes were identified and localized in expression to the developing heart. Transgenic mice lacking a *tinman* homologue (*NKX2.5*) do not lack a heart but die at 9 days of development with a severely abnormal heart.[25] Humans in whom the *tinman* homologue *NKX2.5* is mutated suffer atrial septal defects with associated AV conduction delay.[38] The fruit fly findings led to the study of a set of genes critically important in many aspects of human heart development.

The Tubular and Looping Heart

Tubular morphogenesis is initiated as two epithelia form a tube-within-a-tube structure from the migrating primordial heart tissue. Concurrent with this process, endocardial and myocardial cells—which form the layers of the developing heart—emerge from a common precursor.[23] This tissue progression requires cell differentiation, sorting, and polarization. Evidence supports both negative and positive influences from the surrounding neural tissue and endoderm on these processes.

During the tubular heart stages, the primordia of the peripheral cardiac structures continue to be added sequentially

TABLE 45–1 Developmental Landmarks in Cardiac Morphogenesis

Week	Days	Somites	Length (mm)*	Stage†	Developmental Events
3	15			VIII	(Primitive streak)
	16				
	17				
	18	1-3	1.5	IX	Blood islands in chorion, stalk, yolk sac

from the proximal to the distal at both the arterial and venous ends. The myocardial cells of the tubular heart begin very early to express cardiac-specific cytoskeletal components.

How is this program for cardiac muscle differentiation turned on and regulated? This question has been approached by studying the transcription factors that bind to promoter regions of the cardiac-specific cytoskeletal genes coding for molecules that appear in the early tubular heart. The discovery of myoD, a helix-loop-helix DNA-binding protein that controls skeletal muscle expression, led investigators to search for similar factors in cardiac muscle. To date, no such single factor has been defined. Current findings support the idea that both positive and negative regulators of cardiac genes exist and that they work in complexes that define the spatiotemporal pattern of expression of cardiac genes (see Fig. 45-2).

Closely related to the question of cardiac-specific gene regulation is the question of regional specification of the heart tube. Segmentation, although not as obvious in the vertebrate heart as it is in the insect body plan, is important in cardiogenesis. Chamber-specific expression of a number of endogenous genes and promoter-driven reporter genes suggests that the

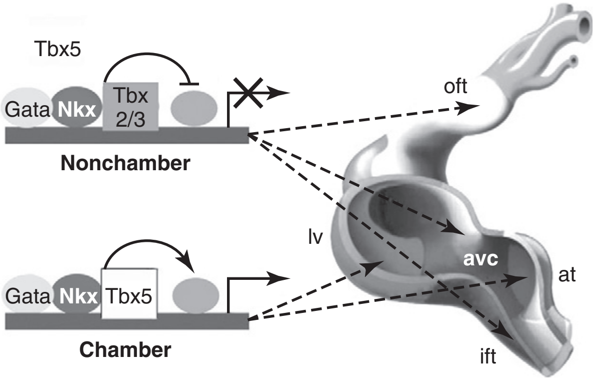

Figure 45–2. Model of transcription regulation of cardiac chamber and nonchamber genes. *NKX2.5, GATA4,* and *TBX5* are widely expressed in the developing heart and promote chamber-specific gene expression (chamber), whereas *TBX2* and *TBX3* are differentially expressed and inhibit chamber-specific gene expression by competing with *TBX5* binding (nonchamber). Chambers are the left ventricle (lv) and the atrium (at). Nonchamber regions include the outflow tract (oft), atrioventricular canal (avc), and inflow tract (ift). These proteins bind to DNA at specific sequences that are involved in controlling gene expression. The combinatorial effect of the binding of these proteins depresses or stimulates the transcription of cardiac-specific genes. *(Modified from Dunwoodie SL: Combinatorial signaling in the heart orchestrates cardiac induction, lineage specification and chamber formation,* Semin Cell Dev Biol *18:54, 2007; originally from Christoffels, et al: Architectural plan for the heart: early patterning and delineation of the chambers and the nodes,* Trends Cardiovasc Med *14:301, 2004.)*

outflow tract (OFT), the left and right ventricles, the atria, and the sinus venosus can in some cases be considered separate cardiac segments. However, many of the endogenous cardiac genes do not strictly follow chamber-specific expression but rather appear to be modularly controlled based on their position along the anteroposterior axis.[17]

An understanding of segment specification has been greatly advanced by the study of the homeobox genes in the fruit fly.[1] The identity and differentiation of segments are determined by interactions among homeobox and other genes. These interactions occur between the mesoderm, which gives rise to the heart tissues, and the tissues adjacent to the mesoderm.

The vertebrate heart tube normally loops to the right side of the embryo. Sidedness appears to be influenced by factors acting at a time when the heart is not recognizable as a distinct organ structure.[36] Transplantation studies using the early chicken embryo suggest that left and right sidedness are already determined in the precardiac mesoderm stages. Sidedness can also be regulated in part by retinoids. Retinoic acid–soaked bead implants in chicken embryos or application of all-*trans* retinoic acid in mouse embryos causes transposition of the great arteries.[20] Abnormalities in the direction of cardiac looping occur in humans.[5] These abnormalities are linked to an autosomal recessive gene defect that has been detected in the Amish population and another gene defect in the X chromosome (Xq24-q27.1) in the general population.[6] Interestingly, abnormalities in genes associated with left-right asymmetry may also be responsible for apparently isolated cases of congenital heart defects. Mutations in the laterality *CFC1* gene have manifested as transposition of the great arteries in humans without other obvious laterality defects.

Two mouse mutants have abnormalities in sidedness. The iv/iv mutant mouse develops L-looping and dextrocardia 50% of the time.[18] A large percentage of these mice have a combination of cardiac defects, including persistent sinus venosus, atrial and ventricular septal defects, common AV canal, double-outlet right ventricle, tetralogy of Fallot, and transposition of the great arteries. This gene has been mapped to mouse chromosome 12, which is homologous to human chromosome 14. The inv/inv mutant mouse develops situs inversus close to 100% of the time.[46] Mutations screens using the zebrafish have uncovered a number of genes involved in laterality specification and indicate that there are organ-specific laterality regulators.[7] Identification of the genes involved in these human, mouse, and zebrafish mutations could provide valuable insight into the mechanisms of normal dextral looping of the heart.[3]

Septation

ENDOCARDIAL DEVELOPMENT: FORMATION OF CUSHION TISSUE

Septation of the heart begins with the swelling of the extracellular matrix between the endocardium and the myocardium at specific regions of the heart tube. These regions include the AV junction, the OFT, the leading edge of the primary atrial septum, and the ridge of the interventricular septum. A complex set of inductive events has been elucidated by studying cushion formation of the AV junction and the OFT.[33] These events include signaling between the specialized myocardium and a subset of competent activatable endocardial cells through growth factors (e.g., transforming growth factor-β, vascular endothelial growth factor) and extracellular matrix molecules. Various proteases and homeobox genes are also involved.

The subsequent cascade of events includes release and migration of cells from the endocardial epithelium (termed *epithelial-mesenchymal transition*) and proliferation and death of these endocardial mesenchyme cells within a complex matrix. In the OFT, the cushions are also populated by cardiac neural crest cells. The endocardial cushions of the AV junction are also invaded by cells originating from the embryonic epicardium. The cushions eventually give rise to—or at least greatly influence—the subsequent development of septa and valves of the heart. Because a number of factors, cell types, and tissues are involved in this process at multiple levels and at different stages, there are many sites where mistakes can occur. It is therefore not surprising that septation defects are so common. The differentiation of resilient valves requires remodeling of the extracellular matrix, an aspect that is poorly understood. However, it has been revealed recently that steps in cardiac valve differentiation and maturation share mechanisms with those of cartilage, tendon, and bone development.[24] The sharing of information across disciplines may therefore lead to rapid advances in understanding cardiac valve development and disease.

NEURAL CREST CONTRIBUTION TO CARDIOGENESIS

A subset of neural crest cells that originate and migrate from the dorsal region of the neural tube contributes significantly to the development of the heart and associated vessels (Fig. 45-3).[19,27] The role of the neural crest has been determined by the study of avian embryos using immunohistochemical neural crest markers, transplantation (quail-chicken chimeras), ablation, and genetic manipulation of mice. The neural crest cells from the cranial and trunk regions contribute to the walls of the aortic arch arteries, including the proximal aorta, the stems of the proximal coronary arteries, and the sympathetic and parasympathetic innervation of the heart (cardiac ganglia). A subset enters the heart within the endocardium and is involved in septation of the aortic and pulmonary trunk. A subset also appears to enter the heart and contributes in some way to the formation of the cardiac conduction system.[16]

Neural crest cells migrate from the cranial region of the neural folds through the pharyngeal arches and contribute to the aorticopulmonary septum and the tunica media of the great arteries that branch from the aorta. Removal of this subset of neural crest cells causes cardiac inflow anomalies, including double-inlet left ventricle, tricuspid atresia, and straddling tricuspid valve; cardiac outflow anomalies, including persistent truncus arteriosus; and abnormalities in the aortic arch arteries, including interruption of the aorta, double aortic arch, variable absence of the carotid arteries, and left aortic arch. In contrast, the systemic and pulmonary venous structures are not as affected by cardiac neural crest ablation.

A more global role for the cardiac neural crest is now recognized after the findings that removal or disturbance of cardiac neural crest cells can influence the function and proliferation of cardiomyocytes before neural crest cells migrate into the heart.[10] Recent findings point to a role for cardiac neural crest–derived cells in influencing the mesenchyme of the secondary or anterior heart–forming field that

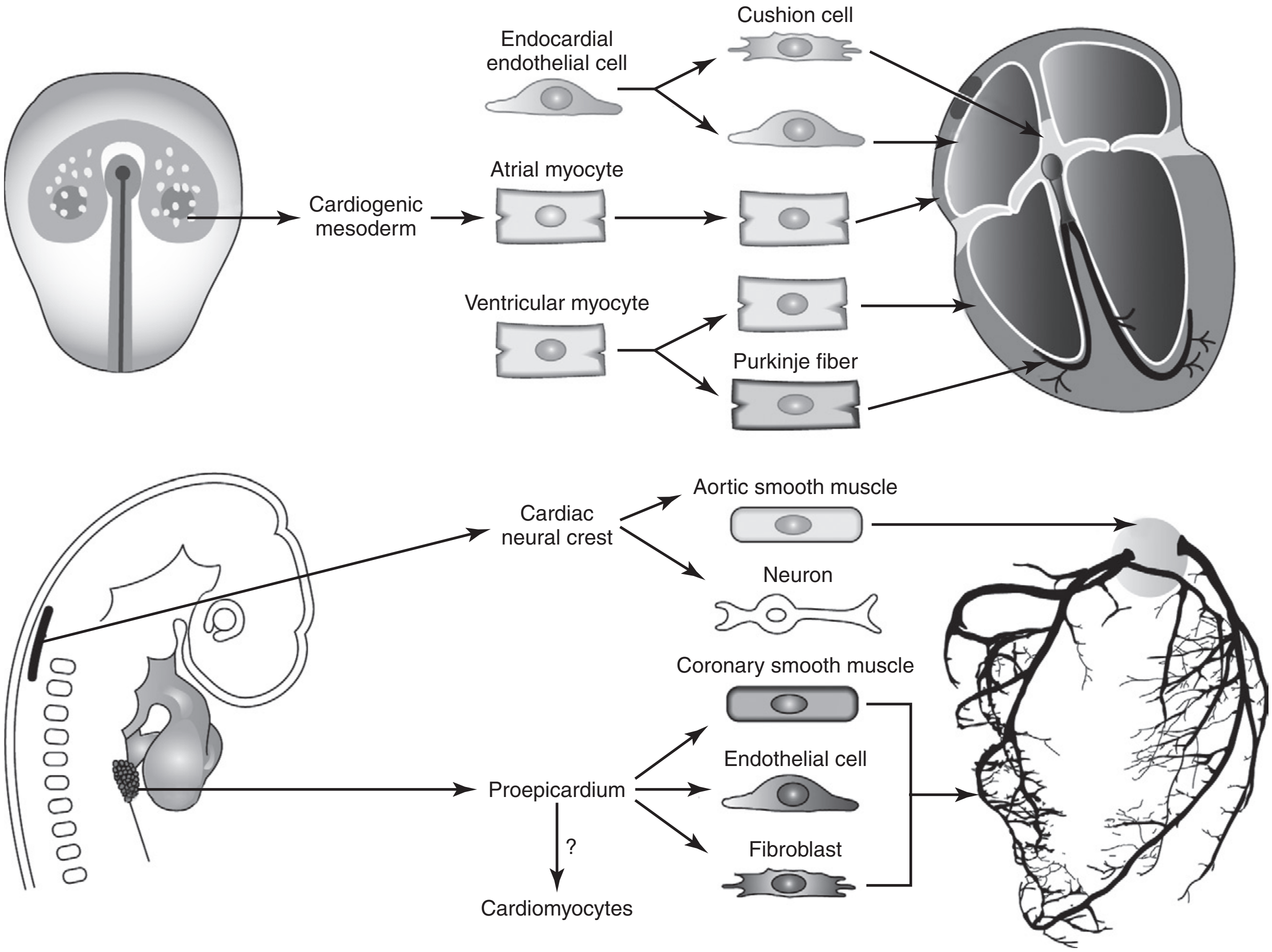

Figure 45–3. Lineage of cardiac cell types. Each cardiac cell type is established by lineage diversification of embryonic cells that arise from one of three distinct origins: cardiogenic mesoderm, neural crest, or proepicardium. This diagram illustrates the chronology and distribution for the development of cell lineages in the avian heart. Newly hypothesized is the epicardial source of a subset of cardiomyocytes. *(Modified from Mikawa T: Cardiac lineages. In Harvey RP, Rosenthal N, editors:* Heart development, *New York, 1999, Academic Press, p 19.)*

produces late-forming cardiac structures, including the outflow tract.[42,47]

Because disturbances of neural crest development have the potential to cause cardiovascular anomalies, factors controlling normal neural crest cell development are receiving much attention. DiGeorge and related syndromes that include craniofacial and OFT abnormalities are believed to result from disruption of neural crest cell development.[13] These syndromes are associated with deletions in 22q11, a region of human chromosome 22 that is under close scrutiny.

The search for "the DiGeorge syndrome gene" has been confounded by the number of candidate genes in the DiGeorge critical region and by the differences between the phenotypes of mice and humans mutated in homologous genes. It is also puzzling that individuals without the deletion can closely resemble those with the DiGeorge region missing. *TBX1* and *CRKL* are currently described as the best candidate genes within the most common 22q11 deletion. However, researchers continue to propose that there is no single affected gene responsible for the defects associated with DiGeorge or the 22q11 deletion syndrome. Rather, a combination of affected genes within that region, as well as those outside that region, appear to regulate the same critical cellular processes. Recent data suggest that many of the mutations identified in individuals with a range of craniofacial and cardiac syndromes that include DiGeorge are in genes associated with the ERK pathway.[2,31] These genes include upstream genes such as *TBX1* and *CRKL* and downstream genes such as *SRF*. A broader hypothesis is emerging that anything that dysregulates the activity of the ERK pathway up or down in developing neural crest cells results in craniofacial and cardiac syndromes.

DEVELOPMENT OF THE CARDIAC CONDUCTION SYSTEM

Primordia of the pulse-generating system function early in the caudal region of the tubular heart and allow unidirectional blood flow, but subsequent events in the development of the cardiac conduction system (CCS) are not well understood. Investigations of CCS embryogenesis in a variety of species, including the mouse, chicken, and zebrafish, have contributed to this understanding.[21] Classic histologic analyses are limited in the information they provide because the early CCS cannot be readily distinguished histologically or even ultrastructurally from the surrounding myocardium. Biochemical markers have been detected that transiently stain portions of the CCS and have been used to follow these tissues during the three-dimensionally complex morphogenesis of the heart. The rabbit model is unique in that there is a marker for it, NF-150, an antibody to neurofilament proteins, that delineates its cardiac conduction system throughout its development and into the adult. These markers show that some of the tissues that give rise to the CCS can be distinguished from other cardiomyocytes as early as the tubular heart stages because they have a different pattern of gene expression and cell proliferation.

The role of the differentially expressed CCS markers is still not understood; nevertheless, the markers have clarified issues about normal and abnormal morphogenesis. Marking the early CCS by using the markers' specific properties has allowed the CCS to be used as a point of reference to deduce which portion of the heart is growing and moving relative to others.[30]

Lineage tracing of myocardial cells provided clues to the origin of the CCS. The clonal relationship between CCS cells and working cardiomyocytes suggests that these specialized myocardia can be recruited from unspecialized myocardial cells. Evidence from avian systems supports the hypothesis that the vasculature can be the source of factors that initiate such recruitment, with endothelin-1 being a strong candidate for signaling.[14]

Less is known about the physiology of the developing CCS primarily because of technical barriers to resolution. This barrier is, however, being overcome by advances in biomedical engineering technologies such as optical mapping using voltage-sensitive fluorescent dyes and optical coherence tomography that allow the capture of images of the tiny beating heart at high spatiotemporal resolution. Different strategies are used by the embryo at different stages of cardiogenesis for coordinating the contraction of the heart. The tubular heart has a peristaltic-type contraction pattern resulting from a pulse-generating focus of cells and a slow distribution of action potentials radiating evenly from that region in all directions.[22] In the septating heart, alternating regions of relatively slow and fast conduction allow pumping of blood in one direction, with the endocardial cushions acting as primitive valves. Slow regions cause a delay of the impulse between the sinus venosus and atrial and ventricular chambers and through the OFT.[11] The ventricular conduction system achieves its mature morphology simultaneous with the appearance of the mature sequence of activation.[9] Subsequent differentiation allows for increasing speed of action potential conduction through the fascicular portion of this system and compensation for the growth of the heart. Maturation of the fibrous ring that separates the atrial from ventricular muscle and the connective tissue sheath around the conduction system also follows.

EPICARDIUM

The epicardium is a relatively late-forming cardiac tissue that does not appear until septation is underway. It provides the bulk of the noncardiomyocyte cellular components, including smooth muscle cells, fibroblasts, and endothelial cells. The progression of epicardial development has been studied in detail using avian and mouse models. The epicardium, the outer layer of the heart, forms by the growth of epithelial tissue from the dorsal mesothelium of the sinus venosus region. This single-cell layer spreads in a stereotyped pattern over the myocardium. The squamous epithelium of the primitive epicardium and the myocardium are initially juxtaposed, but a rapid accumulation and differentiation of connective tissue components between these layers ensues to thicken the epicardium. The cells of the epicardium invade the myocardium and the endocardium, giving rise to fibroblasts, smooth muscle cells, and all components of the coronary vasculature.[26] The epicardium is also the tissue in which cardiac ganglia develop, nerves travel, and fat cells accumulate. Recently, new evidence suggests that the embryonic epicardium may also include cells that can contribute a subset of cardiomyocytes.[4,48] This interesting tissue and its interaction with the myocardium are the focus of much current research.

LYMPHATICS

Although it is known that the adult vertebrate heart is incorporated with an extensive lymphatic network, the lymphatic vasculature of the embryonic heart has not been investigated in detail. The mature heart is thought to have two plexuses: (1) the deep plexus immediately under the endocardium, and (2) the superficial plexus subjacent to the visceral pericardium.[15,28] The deep plexus opens into the superficial plexus, whose efferent vessels will form right and left collecting trunks. The study of lymphatic development during cardiogenesis is now revived with the identification of lymphatic markers. This area of study is in its early stages. One of the many questions not yet answered in this field is, where do the lymphatic precursors come from? Lymphatic cells, whether or not they originate in the epicardium, do end up in the epicardium surrounding coronary vessels. An understanding of the mechanisms driving development of the lymphatic vasculature of the developing heart and of lymphangiogenesis in this region may help in treating edema or similar conditions in the future.

CELL DIVISION AND CELL DEATH

Differential control of cell division and cell death can in part account for the enormous differences in morphologic features of the various regions of the heart. For example, the cells of the thin-walled atria divide less than the cells of the thick-walled ventricle. The central structures of the fascicular CCS slow their proliferation rate early compared with surrounding myocardium.[39]

Apoptosis—programmed cell death—is a developmentally controlled strategy in the morphogenesis of many structures. It occurs during the pruning of the nervous system and the sculpting of digits, and it occurs at many sites throughout cardiogenesis.[34] Endocardial mesenchyme cells, which include cardiac neural crest cells, undergo a high level of apoptosis during septation. A high frequency of apoptosis of cardiomyocytes occurs coincident with OFT morphogenesis. Experimental manipulation to increase or decrease cell death at this stage results in conotruncal abnormalities.[37] Thus, regulated apoptosis of OFT cardiomyocytes is critical for the normal docking of the great arteries with the ventricles. Environmental and genetic factors that alter the level of apoptosis at these critical stages and sites in the developing heart may contribute to congenital heart defects.

HUMAN GENETICS

The entire human genome is sequenced, and efforts have been made to allow clinicians, basic scientists, industry scientists, and others to tap into the database and exchange information. Knowledge of the human genome helps in predicting potential problems, forming the basis for the growing field of genetic counseling. In addition, the study of human genetics allows identification of regions of the genome that might be adversely affected in patients with heart disease. Eventually, this information may be used in developing therapies for heart disease. Comparison of the human genome sequences with those of many other species has also provided important information. Sequences conserved across species often indicate regions of a gene that are critical for a particular function and are worth focused scrutiny. The field of human genetics also provides information for the basic sciences, the "bedside to the bench" links. Genetic analysis of individuals with certain syndromes can pinpoint genes and proteins that can be studied in detail to identify critical functions.

Therapy

Strategies to repair heart tissue are relevant to both pediatric and adult cardiology and have been the focus of much effort. The problem is that human myocardial cells lose their ability to divide soon after birth. This terminal differentiation appears to be irreversible. It had been believed that, within adult heart tissue, no stem cells existed that could be activated to replace defective or damaged cardiomyocytes. Inspired by new information, investigators are seeking ways to initiate cell division in cardiomyocytes or to initiate myocardial differentiation in fibroblasts by turning on or off gene expression of various factors. Fibroblasts are being considered because they continue to divide, are abundant in the postnatal and adult myocardium, and have been successfully transdifferentiated into skeletal muscle by initiating expression of the transcription factor myoD. A proposed treatment of muscular dystrophy involves seeding healthy stem cells, embryonic or fetal cells, or genetically engineered cells into unhealthy tissues.

Heart tissue also appears amenable to such strategies. Myocardial cells (cell lines or embryonic myocytes) can integrate to some extent into the adult heart of animal models. Thus, they undergo some differentiation and integration in a foreign environment. Findings suggest that stem cells exist in the interstices of the adult heart and can be capable of differentiating into cardiomyocytes.[32] Endothelial cells, bone marrow cells, and umbilical cord cells are known to differentiate into cells with cardiac markers and are under study as potential candidates for use in cardiac tissue repair. Recent studies provide evidence that epicardial progenitor cells may have the capacity to contribute to the cardiomyocyte lineage in the developing heart.[4,48] Furthermore, investigators were able to induce the differentiation of adult epicardial cells into endothelial cells.[41] These findings suggest different strategies for therapy. The question remains whether any of these cells will be able to differentiate, integrate, and function appropriately in the adult heart as cardiomyocytes or endothelial cells without becoming malignant. The potential for causing cancer or arrhythmias is possible with some of these therapies.

A newly exploding area of research is the study of micro-RNAs and their potential therapeutic value.[44,45] Micro-RNAs are single-stranded RNAs, about 22 noncoding nucleotides in length, that are present endogenously. They act as specific regulators of gene expression in development and disease by interfering with translation of messenger RNAs or by enhancing the degradation of messenger RNAs. The ability of a particular micro-RNA to regulate RNAs from related sets of genes has raised the possibility that manipulating the levels of micro-RNAs may be a comprehensive strategy to prevent or reverse complex disease. Intriguing is the finding that sequences for micro-RNAs are found within the very genes that they control.

Gene therapy, in combination with intravascular stents, is being considered for treatment of coronary and peripheral vascular disease in adults. Exogenous genes can be introduced by a variety of means to the heart or vasculature. In vitro studies or those in animal models have also shown that physiologically significant genes (e.g., plasminogen activator) can be introduced and cause significant levels of protein expression for enough time to have therapeutic effects.

The most controversial approach for therapy involves manipulating the genome of the germ cells so that the entire embryo can go through development with the corrected gene. This approach requires that the manipulation result in little or no effect besides the desired effect. Introducing the gene into a genome can by itself cause inadvertent wide-ranging defects. Such methods also require a thorough understanding of the gene being manipulated so that all controlling elements, as well as the structural portion of the gene, are intact.

Another strategy in preventing congenital heart defects is to correct at a level farther along the pathway from the genome. This can be done by turning on alternative biochemical pathways or by boosting compensatory mechanisms. This approach requires a thorough understanding of the network of pathways and all of its interactions and feedback loops.

Finding the appropriate strategy for therapy is complicated because defects involve a combination of genes and environmental factors and include direct and indirect effects that are difficult to control with current knowledge and techniques. However, with the great and often serendipitous advances in our understanding of cardiovascular development, certain defects might be preventable or reversed in our lifetime.

PART 2

Pulmonary Vascular Development

Robin H. Steinhorn

Normal prenatal and postnatal development of pulmonary vascular structure and function is essential for the lung to perform its basic physiologic function of allowing gas exchange across a thin blood-gas interface. Survival of the newborn is therefore dependent on rapid adaptation of the fetal cardiopulmonary system to the demands of extrauterine life, and on sustained low pulmonary vascular resistance (PVR) as postnatal development continues.

FETAL PULMONARY VASCULAR DEVELOPMENT

Structural Development

Fetal lung development is classically described as occurring in five distinct but overlapping stages: embryonic, pseudoglandular, canalicular, saccular, and alveolar. Pulmonary vascular development begins during the embryonic phase of lung development. Endodermal lung buds arise from the ventral aspect of the foregut by the fifth week of gestation. The pulmonary trunk, derived from the truncus arteriosus, divides into the aorta and pulmonary trunks by 8 weeks of gestation by growth of the spiral aortopulmonary septum.[48] The pulmonary trunk connects to the pulmonary arch arteries, which are derived from the sixth branchial arch arteries. The mesenchyme surrounding the lung bud then develops into the vascular network.

As gestation progresses, there is close synchronization between the development of the pulmonary arterial tree and airway branching. In the human lung, the preacinar vascular branching pattern is present by the 20th week of fetal life.[23] In contrast, intra-acinar arteries form later in fetal life and after birth during the alveolar phase of lung development.[22] Airway and vascular development are highly interactive processes, and disrupted development of one system is likely to have important consequences on the development of the other, ultimately affecting lung structure and function. Development of the pulmonary veins parallels that of the arteries, but they arise separately from the loose mesenchyme of the lung septa and subsequently connect to the left atrium.[11]

Angiogenesis and vasculogenesis are two distinct morphogenetic processes that contribute to the development of the pulmonary vasculature. Vasculogenesis is the de novo organization of blood vessels by in situ differentiation of endothelial progenitor cells (angioblasts) from the mesoderm. These angioblasts migrate, adhere, and form vascular channels that become arteries, veins, or lymphatics depending on the local factors within the mesenchyme.[36] Endothelial precursor cells, after differentiation into the endothelium, either contribute to the expression of smooth muscle phenotype in the surrounding mesenchyme or recruit existing smooth muscle cells to the forming vessel.

Angiogenesis refers to the budding, sprouting, and branching of the existing vessels to form new ones. New evidence indicates that vasculogenesis and angiogenesis are not necessarily sequential processes, and that both may occur early in lung development, perhaps giving rise to heterogeneous cell populations in the vasculature.[49] In addition, a process of vascular fusion has been described that connects the angiogenic and vasculogenic vessels to allow for expansion of the vascular network.[11,48] Numerous local growth and transcription factors, such as vascular endothelial growth factor, transforming growth factor-β, fibroblast growth factors, platelet-derived growth factor, angiopoietin, and others, play an important role in vascular development and cell differentiation in the developing lung.[7,51] Growth factor function is also regulated through specific receptors, including the bone morphogenetic protein receptor-2 (BMPR2), a receptor for the transforming growth factor-β superfamily. Mutations of

BMPR2 are now known to be associated with familial and idiopathic pulmonary hypertension in adults and children.[32]

As gestation and fetal lung growth progress, the number of small pulmonary arteries increases, both in absolute terms and per unit volume of the lung.[30] In fetal lambs, lung weight increases 4-fold during the last trimester, whereas the number of small blood vessels in the lungs increases 40-fold. Thus, the number of small blood vessels within each lung increases 10-fold, preparing the lungs to accept the 10-fold increase in blood per unit of lung that occurs at birth. This increase in the capacity of the pulmonary arteries indicates that vascular constriction must play a key role in maintaining high pulmonary vascular tone during fetal life.

Mediators of Fetal Pulmonary Vascular Tone

Pulmonary hypertension is normal and necessary for the fetus. Because the placenta serves as the organ of gas exchange, most of the right ventricular output in the fetus bypasses the lung and crosses the ductus arteriosus to the aorta. Pulmonary pressures are equivalent to systemic pressures due to elevated PVR, and only about 10% of the combined ventricular output is directed to the pulmonary vascular bed.

Multiple mechanisms are in place to maintain low pulmonary blood flow in the fetus. The low oxygen environment of the fetus almost certainly plays a key role in maintaining high PVR. Normal fetal oxygen tension is about 25 mm Hg, a level that promotes normal growth and differentiation of pulmonary vascular cells and supports normal branching morphogenesis in the fetal lung.[18] Because oxygen regulates activity of enzymes such as nitric oxide synthase, the low oxygen environment of the fetus may maintain low production of vasoactive mediators such as nitric oxide and prostacyclin. For instance, a modest increase in PaO_2 (to levels of about 50 mm Hg) in the near-term fetal lamb activates nitric oxide synthase and increases pulmonary blood flow to levels comparable to postnatal lambs.[52] The fetal pulmonary circulation also exhibits a marked myogenic response as gestation progresses, meaning that the vasculature responds to vasodilatory stimuli with active vasoconstriction.[50]

Vasoactive mediators likely play an important role in maintaining the normal patterns of fetal circulation. Although it is assumed that vasoconstrictors help maintain high pulmonary vascular tone in utero, surprisingly little is known about their specific roles throughout gestation. Some of the proposed fetal pulmonary vasoconstrictors include endothelin-1, as well as vasoconstrictor products of arachidonic acid metabolism such as thromboxane and leukotrienes. It is also possible that low basal production of vasodilators such as nitric oxide or prostacyclin may maintain high PVR, although it is interesting to note that this low production occurs despite an increase in pulmonary expression of endothelial nitric oxide synthase and cyclooxygenase-1 during late gestation. Recent evidence points toward a critical role for the RhoA/Rho kinase signal transduction pathway,[39] a central downstream pathway that promotes vasoconstriction through inactivation of myosin light chain phosphatase, thus increasing calcium sensitivity of the smooth muscle cell.

PULMONARY VASCULAR TRANSITION

At birth, a rapid and dramatic decrease in PVR allows half of the combined ventricular output to be redirected from the placenta to the lung, leading to an 8- to 10-fold increase in pulmonary blood flow. Increased pulmonary blood flow increases pulmonary venous return and left atrial pressure, promoting functional closure of the one-way valve of the foramen ovale. Systemic vascular resistance increases at birth, at least in part because of removal of the low resistance vascular bed of the placenta.

The largest drop in PVR occurs shortly after birth, although resistance continues to drop over the first several months of life until it reaches the low levels normally found in the adult circulation. As PVR falls below systemic levels, blood flow through the patent ductus arteriosus reverses. Over the first several hours of life, the ductus arteriosus functionally closes, largely in response to the increased oxygen tension of the newborn. This effectively separates the pulmonary and systemic circulations and establishes the normal postnatal circulatory pattern.

The stimuli that appear to be most important in decreasing PVR are lung inflation with a gas and an increase in oxygen tension. Each of these stimuli by itself will decrease PVR and increase pulmonary blood flow, with the largest effects seen when the two events occur simultaneously. Mechanical distention of the lungs initiates the process of rapid structural adaptation of the pulmonary vessels. The external diameter of the nonmuscular arteries increases, and the prominent endothelial cells assume a flattened appearance (Fig. 45-4). There is an increase in cell length and surface-to-volume ratio as the cells spread within the vessel wall to increase lumen diameter and lower resistance.[4] This process is likely facilitated by the paucity of interstitial connective tissue, allowing for greater plasticity of the vessel. In postmortem arterial-injected specimens, the number of nonmuscular arteries that fill with injection

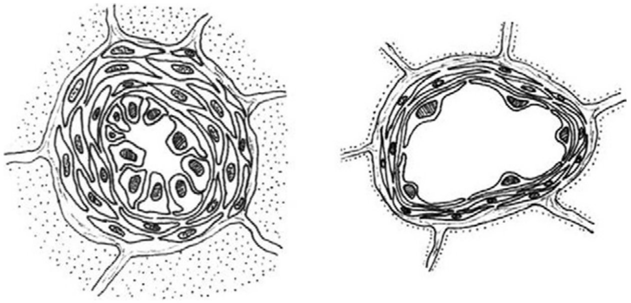

Figure 45–4. Changes in the small muscular pulmonary arteries during transition. Muscularized small pulmonary arteries from a near-term gestation fetus (*left*) demonstrate swollen endothelial cells and increased thickness of the muscular layer. Within 24 hours after birth (*right*), a considerable increase in luminal diameter is noted secondary to flattening of the endothelial cells, spreading of the smooth muscle cells, and an increase in external diameter due to relaxation of the smooth muscle. These events contribute to the drop in pulmonary vascular resistance after birth. *(From Lakshminrusimha S, et al: Pulmonary vascular biology during neonatal transition,* Clin Perinatol *26:601, 1999.)*

material increases rapidly during the first 24 hours, suggesting that there is a rapid increase in the number of precapillary arteries recruited into the pulmonary circulation after birth.[21]

An increase in oxygen tension will reduce PVR independent of the effects of lung inflation. This oxygen response emerges at about 70% gestation in the fetal lamb and continues to develop as gestation progresses.[35] As noted earlier, the full vasodilatory effect of oxygen can be achieved with quite modest increases in arterial concentrations: $\mathrm{PaO_2}$ levels of about 50 mm Hg in the near-term fetal lamb will decrease pulmonary vascular resistance and increase pulmonary blood flow to levels comparable to those in postnatal lambs.[52] Evidence indicates that in addition to facilitating vasodilation, oxygen may also promote the rapid endothelial spreading and remodeling described previously.[56]

Finally, the initial increase in pulmonary blood flow increases shear stress in the pulmonary vasculature, which further promotes rapid vasodilation in the pulmonary circulation of the newborn and late-gestation fetus.[1] The mechanisms of shear stress–mediated responses are complex but appear to involve stimulation of K^+ channels and activation of nitric oxide synthases.[6,53]

Vasoactive Mediators of the Pulmonary Vascular Transition

No single vasoactive agent has been identified as the primary mediator of transitional pulmonary vasodilation; rather, it is believed that numerous factors interact to facilitate the mechanical events described earlier. Increases in vasodilators appear to be more important than decreases in vasoconstrictors; of these, nitric oxide has emerged as one of the most important. Pulmonary expression of all three isoforms of nitric oxide synthase and its receptor molecule, soluble guanylate cyclase, increase late in gestation. Increased nitric oxide production serves to activate soluble guanylate cyclase and increase concentrations of the second messenger cyclic guanosine monophosphate (cGMP) in vascular smooth muscle cells. cGMP then initiates the cascade that decreases intracellular calcium and produces vasorelaxation. Acute or chronic inhibition of nitric oxide synthase in fetal lambs produces pulmonary hypertension after delivery, illustrating the critical importance of the nitric oxide–cGMP pathway in facilitating normal transition.[2,16] Data indicate that low fetal nitric oxide synthase activity may be maintained during fetal life in part through increased levels of asymmetric dimethyl arginine, a endogenous competitive inhibitor of nitric oxide synthase.[5,40] Expression of cGMP-specific phosphodiesterases also increases during late lung development, possibly serving to mediate tight regulation of intracellular cGMP concentrations and signal transduction at birth.[42]

Prostacyclin is a second central vasodilator that is upregulated in response to ventilation of the lung. Cyclooxygenase and prostacyclin synthase generate prostacyclin from arachidonic acid. Cyclooxygenase-1 in particular is upregulated during late gestation, leading to an increase in prostacyclin production in late gestation and early postnatal life.[8,29] Prostacyclin stimulates adenylate cyclase to increase intracellular cyclic adenosine monophosphate (cAMP) levels, which, as with cGMP, leads to vasorelaxation through a decrease in intracellular calcium concentrations.

ABNORMALITIES OF PULMONARY VASCULAR DEVELOPMENT

Persistent Pulmonary Hypertension of the Newborn (See also part 8)

Persistent pulmonary hypertension (PPHN) describes the failure of normal pulmonary vascular adaptation at birth. This syndrome complicates the course of about 10% of term and preterm infants with respiratory failure and remains a source of considerable mortality and morbidity. PPHN can be generally characterized as one of three types: (1) the abnormally constricted pulmonary vasculature due to lung parenchymal diseases, such as meconium aspiration syndrome, respiratory distress syndrome, or pneumonia; (2) the lung with normal parenchyma and remodeled pulmonary vasculature, also known as idiopathic PPHN; or (3) the hypoplastic vasculature as seen in congenital diaphragmatic hernia. Although idiopathic pulmonary hypertension is responsible for only 10% to 20% of all infants with PPHN, severe cases of PPHN associated with parenchymal disease are complicated by a significant degree of vascular remodeling.

Pulmonary vascular remodeling occurs antenatally in infants presenting with severe PPHN shortly after birth. Pathologic findings include significant remodeling of the pulmonary arteries, characterized by vessel wall thickening, and smooth muscle hyperplasia. An important feature includes extension of the smooth muscle to the level of the intra-acinar arteries (Fig. 45-5), which does not normally occur until much later in the postnatal period.[38] One cause of idiopathic PPHN is constriction of the fetal ductus arteriosus *in utero*, which can occur after exposure to nonsteroidal anti-inflammatory drugs during the third trimester.[3,31] Because it is difficult to gain sufficient mechanistic insights in the clinical setting, animal models have provided valuable insights into the antenatal and postnatal vascular abnormalities associated with PPHN. Ductal constriction or ligation can be surgically performed *in utero* in lambs and produces rapid antenatal remodeling of the pulmonary vasculature. Pathologic and physiologic findings in PPHN lambs are similar to those observed in human infants, including increased fetal pulmonary artery pressure, pulmonary vascular remodeling, and profound hypoxemia after birth.

New data suggest that maternal exposure to selective serotonin reuptake inhibitors during late gestation is associated with a sixfold increase in the prevalence of PPHN,[10] although it is not clear how many infants developed severe disease. Newborn rats exposed *in utero* to fluoxetine develop pulmonary vascular remodeling, abnormal oxygenation, and higher mortality when compared with vehicle-treated controls.[17] Because selective serotonin reuptake inhibitors have been reported to reduce pulmonary vascular remodeling in adult models of pulmonary hypertension, these findings also serve to highlight the unique vulnerability of fetal pulmonary vascular development.

Disruptions in the production or function of vasoactive mediators at birth will also lead to pulmonary vasoconstriction. Based on work from animal models and human infants, there is strong evidence that disruptions of the nitric oxide–cGMP,

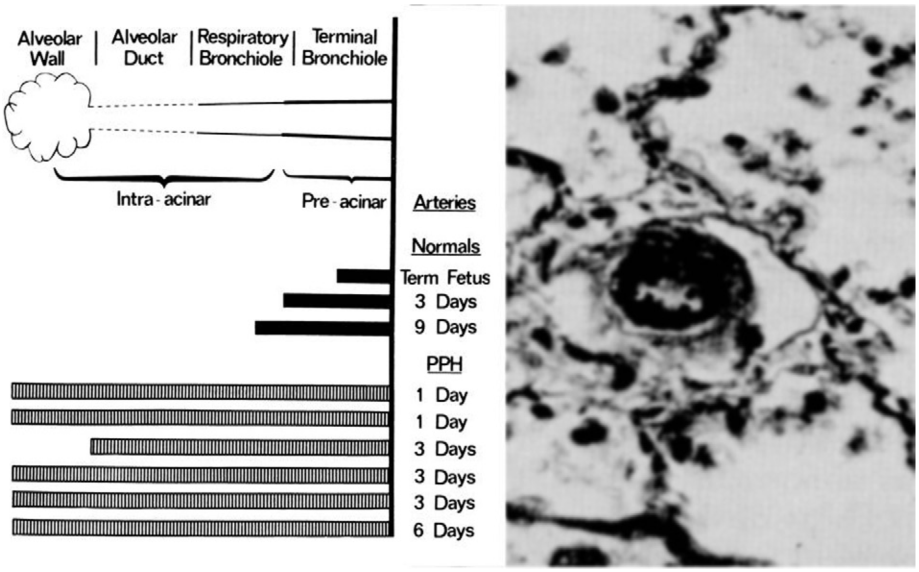

Figure 45–5. Vascular maldevelopment is a hallmark of persistent pulmonary hypertension (PPH). The pulmonary vessels show thickened walls with smooth muscle hyperplasia. Further, the smooth muscle extends to the level of the intra-acinar arteries, which does not normally occur until much later in the postnatal period. *(From Murphy JD, et al: The structural basis of persistent pulmonary hypertension of the newborn infant,* J Pediatr *98:962, 1981.)*

prostacyclin-cAMP, and endothelin signaling pathways play an important role in the vascular abnormalities associated with PPHN. The nitric oxide–cGMP pathway has been a topic of particularly intense investigation over the past decade, at least in part because of the ability to deliver exogenous (inhaled) nitric oxide as a therapeutic agent. Decreased expression and activity of endothelial nitric oxide synthase have been documented in animal models,[45,54] and decreased endothelial nitric oxide synthase expression has been reported in umbilical venous endothelial cell cultures from human infants with meconium staining who develop PPHN.[12] There is also evidence that PPHN is associated with disruptions of endothelial nitric oxide synthase activity through "uncoupling" of the enzyme, which not only reduces synthesis of nitric oxide but also promotes production of reactive oxygen species, such as superoxide. Further, the vascular abnormalities appear to include downstream alterations in accumulation of the critical second messenger, cGMP. For instance, vessel studies from PPHN lambs suggest that soluble guanylate cyclase is less sensitive to nitric oxide, meaning that cGMP concentrations are reduced in the diseased vascular smooth musculature, even when exogenous nitric oxide is administered.[47] In addition to decreased cGMP production, increased activity of phosphodiesterase-5 has been reported in animal models, which would further decrease cGMP concentrations by increasing its inactivation.[20]

Although prostacyclin appears to be important in the normal pulmonary vascular transition, less is known about the role of abnormal prostacyclin-cAMP signaling in PPHN. Some data suggest abnormalities in prostacyclin synthesis and downstream adenylate cyclase responses exist, analogous to the abnormalities reported for nitric oxide–cGMP signaling.[28,44] In addition, production of the vasoconstrictor arachidonic acid metabolite, thromboxane, plays a role in pulmonary hypertension produced by chronic hypoxia.[14]

Circulating levels of the potent vasoconstrictor endothelin-1 are elevated in lambs and newborn infants with PPHN.[27,41] Endothelin-1 effects are mediated through two receptors, endothelin-A receptors on smooth muscle cells that mediate vasoconstriction and endothelin-B receptors on endothelial cells that mediate vasodilation. There is evidence that the balance of endothelin receptors is shifted to the vasoconstrictor (endothelin-A) pathways.[24] In addition, endothelin may affect vascular tone by increasing production of reactive oxygen species such as superoxide and hydrogen peroxide, which also act as vasoconstrictors.[55] Therefore, the elevated endothelin levels in PPHN may increase vasoconstriction through preferential stimulation of endothelin-A receptors and through increased production of superoxide.

There is mounting evidence that oxidant stress plays an important role in the pathogenesis of PPHN. An increase in reactive oxygen species such as superoxide and hydrogen peroxide in the smooth muscle and adventitia of pulmonary arteries has been demonstrated in animal models of pulmonary hypertension.[9,15] Possible sources for elevated concentrations of reactive oxygen species include increased expression and activity of NADPH oxidase, uncoupled nitric oxide synthase activity, and a reduction in superoxide dismutase activity. Once present in the lung, elevated concentrations of reactive oxygen species promote vasoconstriction directly and by increasing production of other constrictors such as isoprostanes. Reactive oxygen species also increase vascular smooth muscle cell proliferation and blunt cGMP accumulation through increased activity of cGMP-specific phosphodiesterases.[13]

Congenital Diaphragmatic Hernia

(see also Chapter 44.)

Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in 3000 births, and represents ~8% of all major congenital anomalies. CDH is an abnormality of diaphragm development, resulting in a defect that allows abdominal viscera to enter the chest and compress the lung. Herniation occurs most often in the posterolateral segments of the diaphragm, and 80% of the defects occur on the left side. While *in utero* compression of the lung is typically believed to produce lung hypoplasia, there is some evidence that the lung hypoplasia may be a primary event that occurs independently of the diaphragmatic defect. Severe CDH develops early in the course of lung development, and an arrest in the normal pattern of airway branching is noted in both lungs, associated with reduced lung volume and impaired alveolarization.

Because development of the pulmonary arterial system parallels development of the bronchial tree, a similar developmental arrest occurs in pulmonary arterial branching, resulting in a reduced cross-sectional area of the pulmonary vascular bed. Further, the media and adventitia of small arterioles are thickened, and abnormal medial muscular hypertrophy extends as far distally as the acinar arterioles.[34] Functionally, pulmonary blood flow is decreased because of the hypoplastic pulmonary vascular bed, as well as by abnormal pulmonary vasoconstriction. The mediators of altered pulmonary vascular reactivity in CDH are not well understood, although most evidence points to similar patterns of disruption of nitric oxide–cGMP and endothelin signaling as described previously for PPHN.

Abnormalities of cardiac development and function also play an important role in the pathophysiology of CDH. The left ventricle, left atrium, and intraventricular septum are hypoplastic in infants that die from CDH relative to age-matched controls,[46] perhaps owing to low fetal and postnatal pulmonary blood flow as well as compression by the hypertensive right ventricle. Left ventricular hypoplasia and dysfunction would be expected to increase left atrial and pulmonary venous pressure, and this unique feature of CDH may explain the relatively poor responses to inhaled nitric oxide during the first few days of life. Some infants may have exceptionally severe left ventricular dysfunction that leads to dependence on the right ventricle for systemic perfusion; this subset may benefit from clinical strategies that maintain patency of the ductus arteriosus.

Alveolar Capillary Dysplasia

Alveolar capillary dysplasia refers to a rare developmental abnormality of the lung that typically presents as severe idiopathic PPHN. It was first described by this name in 1981[25] and is believed to be a universally fatal condition. It is now recognized that the pulmonary phenotype is relatively consistent and includes a paucity of pulmonary capillaries, increased muscularization of pulmonary arterioles, simplification of the pulmonary architecture, and malposition of pulmonary veins adjacent to pulmonary arteries ("misaligned veins," Fig. 45-6). More than 50% of infants present with other anomalies, most commonly affecting the genitourinary, cardiovascular, and gastrointestinal systems. The diagnosis can only be made with certainty based on microscopic examination of the lung. Therefore, a complete postmortem evaluation should be recommended for all newborns who die as a result of unexplained pulmonary hypertension, and a lung biopsy should be considered in infants with prolonged, refractory PPHN. Although alveolar capillary dysplasia classically presents in the neonatal period, there is increasing recognition of late presentation at several months of life in some infants. About 10% of infants have a familial association, leading some to propose an autosomal recessive inheritance.[43] While the search for a candidate gene has proven difficult, a recent report showed an association with haploinsufficiency for the forkhead (FOX) transcription factor gene cluster and ACD/MPV associated with additional congenital heart defects and/or gastrointestinal anomalies.[46a]

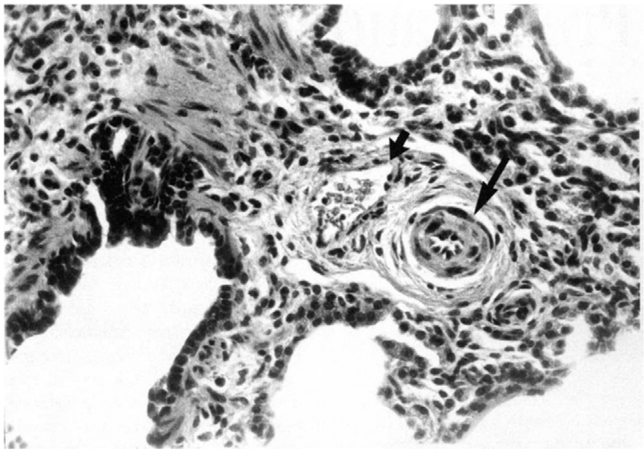

Figure 45–6. Vascular abnormalities associated with alveolar capillary dysplasia. The lung parenchyma shows airspace simplification and widened alveolar walls. A central membranous bronchiole is accompanied by adjacent thick-walled arteries (*long arrow*) with associated dilated veins (*short arrow*). The prominently muscularized arteries extend into adjacent alveolar walls, where they are also accompanied by dilated veins.

Bronchopulmonary Dysplasia

(See also Chapter 44, Part 7.)

Extremely preterm infants (≤26 weeks' gestation) are born during the early saccular phase of lung development; in this setting, much of the saccular and all of the alveolar stages of lung development occur postnatally. Although recent advances in neonatal care have improved survival of this population, they have not reduced the incidence of bronchopulmonary dysplasia (BPD). However, the nature of BPD has changed during the past 2 decades from one defined primarily by lung injury and fibrotic changes to one consisting of abnormal and simplified patterns of alveolarization.

Abnormal vascularization of the lung is now recognized as a critically important component of BPD and is characterized by reductions in the size and number of intra-acinar pulmonary arteries, resulting in a reduced cross-sectional area of the pulmonary vascular bed. There is increasing recognition that abnormal vascular development may precede or promote abnormal lung growth.[19] The morphologic vascular alterations are accompanied by functional changes, characterized by increased pulmonary vascular tone and heightened vasoconstrictor responses to acute hypoxia.[37] Identifying pulmonary hypertension in this population requires a high index of suspicion and careful longitudinal evaluation with echocardiography and cardiac catheterization. Although the incidence and spectrum of pulmonary hypertension associated with BPD remains ill defined, the disease appears to be worst in infants with severe chronic lung disease and in those who are small for gestational age.[26] Further, the presence of severe pulmonary hypertension appears to be associated with exceptionally high mortality in infants with BPD.

Work during the past decade has begun to elucidate early abnormalities of vascular signaling in models of evolving BPD, and downregulation of nitric oxide production appears to be important.[33] Less is known about signaling abnormalities of the remodeled vessel in an infant with established pulmonary hypertension and BPD. Early clinical experience indicates that alterations in the nitric oxide-cGMP, prostacyclin-cAMP, and endothelin pathways will probably all play a role, and these data will be important in developing effective treatment strategies.

PART 3

Genetic and Environmental Contributions to Congenital Heart Disease

Kenneth G. Zahka

Insight into the causes of congenital heart disease can be gained from analysis of genetic and environmental factors[14,15,24,27] and consideration of associated noncardiac abnormalities. Animal models have provided an understanding of the role of a number of gene defects in a variety of transcription factors and signaling molecules that are associated with congenital heart defects. These include the transcription factors NKX2.5, TBX5, GATA4, and FOG2 and the signaling molecules PTPN11, JAG1, and CFC1.[15]

From population-based studies, principally the Baltimore-Washington Infant Study, it is known that more than 25% of infants with congenital heart disease have noncardiac abnormalities.[9] Chromosomal abnormalities and well-defined genetic syndromes constitute two thirds of these cases. The major chromosomal defects are summarized in Table 45-2, although there are many more recognized deletions with a known association with heart disease (see Chapter 29).

Infants with syndromes clearly related to excess or deleted chromosomal material have a pattern of anomalies that are pathogenetically related. Infants who have clusters of defects that appear in a nonrandom fashion and that do not correspond to either syndromes or particular developmental fields during cardiogenesis could have one of several recognized associations. The cause of these associations, including VACTERL (*v*ertebral abnormalities, *a*nal atresia, *c*ardiac abnormalities, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal agenesis and dysplasia, and *l*imb defects)[19,20] is not yet known, although midline defects might represent defects in blastogenesis. Mutations in the *CHD7* gene have been found in most patients with CHARGE association (*c*oloboma, *h*eart disease, choanal *a*tresia, *r*estricted growth and development or other central nervous system anomalies, *g*enital hypoplasia, and *e*ar anomalies or deafness).[18,21]

CHROMOSOMAL DEFECTS

Molecular karyotyping yields an etiological diagnosis in at least 18% of patients with a syndromic CHD. Higher resolution evaluation results in an increasing number of variants of unknown significance.[3a]

The association of congenital heart disease with chromosomal defects, especially trisomies 13, 18, and 21, has been known for many years. Congenital heart defects are not present in all infants with trisomy 21 despite the apparent duplication of genetic material in each child. Equally intriguing is the narrow spectrum of heart defects observed in the 40% of infants with trisomy 21 and congenital heart disease (Table 45-3).[11] Sixty-five percent have endocardial cushion defects, a proportion many times that seen in children with heart defects and normal chromosomes.[30] Furthermore, many defects, including

TABLE 45–2 Major Chromosomal and Inherited Syndromes Associated with Heart Defects

Syndrome	Defects
Trisomy 8	Variable
Trisomy 13	ASD, PDA, VSD
Trisomy 18	ASD, ECD, PDA, TOF, VSD
Turner (XO)	AS, COA, HLHS[31]
Klinefelter (XXY)	MVP, TOF
Deletion 22q11	IAA, TOF, truncus
Marfan (AD, chromosome 15)	Aortic dilation, aortic dilation, TVP
DiGeorge (AD, chromosome 22)	IAA, TOF, truncus arteriosus
Williams (AD, chromosome 7)	Branch pulmonary artery stenosis, supravalvular aortic stenosis[7]
Holt-Oram (AD, chromosome 12)	ASD, COA, VSD[17]
Ellis-van Creveld (AR)	Common atrium
Meckel-Gruber (AR)	AS, ASD, COA, TGA, VSD
Radial aplasia-thrombocytopenia	ASD, TOF
Smith-Lemli-Opitz (AR)	TAPVC
Noonan (AD)	Cardiomyopathy, PS[32]
Kartagener (AR)	Dextrocardia
Neurofibromatosis (AD)	PS, aortic dilation, MVP, HCM[35]

AD, autosomal dominant; AR, autosomal recessive; AS, aortic stenosis; ASD, secundum atrial septal defect; COA, coarctation of the aorta; ECD, endocardial cushion defect; HCM, hypertrophic cardiomyopathy, HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; MVP, mitral valve prolapse; PDA, patent ductus arteriosus; PS, pulmonary valve stenosis; TAPVC, total anomalous pulmonary venous connection; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; TVP, tricuspid valve prolapse; VSD, ventricular septal defect.

transposition of the great arteries and truncus arteriosus, which are common in infants with normal chromosomes, are rare or unreported in children with trisomy 21. The proportion of infants with trisomies 13 and 18 and heart disease is higher than that of infants with trisomy 21, yet the spectrum of defects is also narrower than in the general population.

The understanding of the mechanism of abnormal cardiogenesis is an area of intense interest in cardiovascular genetics. Collagen type VI has been studied for its role in the pathogenesis of heart defects in children with Down syndrome. Studies suggest that genetic variation in the *COL6A1* gene might be associated with an increased prevalence of heart defects.[6] The *SH3BGR* gene on chromosome 21 has been proposed as a critical candidate gene for cardiac defects and hypotonia.[34]

SINGLE GENE DEFECTS

Cardiovascular abnormalities are a feature of a number of syndromes that are clearly due to single gene defects. In Marfan syndrome, the defect has been linked to mutations in the fibrillin gene on chromosome 15.[8] Loeys-Dietz syndrome is a newly described connective tissue disorder due to mutations in the receptor for transforming growth factor-β, which can present in the neonatal period with aortic dilation and mitral valve prolapse.[23] Williams syndrome is associated with a defect in the elastin gene on chromosome 7.[36] Holt-Oram and other hand-heart syndromes have been found on chromosome 12. Holt-Oram syndrome is caused by mutations in the *TBX5* gene, which is believed to be critical for heart and limb development.[17]

Recognition that microdeletions of chromosome 22 are associated with the phenotype of velocardiofacial syndrome[13] and DiGeorge syndrome, both of which have a high prevalence of conotruncal heart defects, has increased the interest in abnormalities of this chromosome as a cause of other conotruncal defects. Goldmuntz and associates screened 250 consecutive children with conotruncal defects and found that 50% of children with interrupted aortic arch, 35% with truncus arteriosus, and 16% with tetralogy of Fallot had a microdeletion of chromosome 22.[12] Children with right aortic arch or aberrant subclavian artery were particularly likely to have a deletion.

Mutations in the *NKX2.5* gene are associated with heart defects and conduction abnormalities.[25] The cardiovascular abnormalities in Alagille syndrome are seen in children with *JAG1* mutation.[26]

TABLE 45–3 Cardiovascular Diagnoses in Infants with Down Syndrome and Isolated Cardiac Malformations

		PERCENTAGE OF PATIENTS WITH DEFECT					
Diagnosis	**No. of Patients**	**CAVSD**	**PAVSD**	**VSD**	**ASD**	**TOF**	**PDA**
Down syndrome	160	51	13	16	10	6	4
Isolated cardiac malformation	540	2	4	58	16	15	6

ASD, secundum atrial septal defect; CAVSD, complete atrioventricular septal defect; PAVSD, partial atrioventricular septal defect; PDA, patent ductus arteriosus; TOF, tetralogy of Fallot; VSD, perimembranous ventricular septal defect.

Adapted from Schneider DS, et al: Patterns of cardiac care in infants with Down syndrome, *Am J Dis Child* 143:363, 1989.

ENVIRONMENTAL TOXINS

Epidemiologic studies have occasionally linked exposure to drugs or environmental toxins to congenital heart defects (see Chapter 12). The timing of exposure during early cardiogenesis is critical, and in some cases, as in exposure to lithium,[2] the evidence remains controversial. Abuse of substances such as ethanol and probably cocaine increases the risk for congenital heart defects. Anticonvulsant therapy with phenytoin and valproic acid is associated with fetal congenital heart defects. Warfarin therapy is a major concern for mothers with congenital heart defects because the risk for congenital heart disease in offspring might be additive with any potential genetic risk.

Prostaglandin synthetase inhibitors, principally indomethacin, have been used in the third trimester to treat premature labor. Transient partial constriction of the fetal ductus arteriosus has been documented by fetal echocardiography and Doppler studies in up to 25% of fetuses during several days of maternal administration of indomethacin.[22] The narrowing resolves after discontinuation of the drug, although prolonged administration to animals can result in right ventricular dysfunction and tricuspid regurgitation as a result of right ventricular hypertension.

MATERNAL DISEASES

Mothers who have diabetes mellitus during cardiogenesis have a twofold to fourfold risk for having babies with congenital heart disease, most commonly ventricular septal defect, transposition of the great arteries, tetralogy of Fallot, and double-outlet right ventricle (see Chapter 16 and Chapter 49, Part 1).[1] The mechanism of this risk is unknown but is presumed to be metabolic abnormalities that occur during critical phases of development. Heart defects are less common in mothers with normal hemoglobin A_{1c} levels.[29] In late gestation, poor control of diabetes increases fetal insulin concentration in response to the increased transplacental glucose load. Insulin is a growth factor for fetal myocardium, and the infants could be born with hypertrophic cardiomyopathy. This myopathy is usually asymptomatic and resolves during the first weeks of life. A small number of infants have significant diastolic dysfunction or dynamic outflow tract obstruction, with tachypnea and signs of congestive heart failure or poor cardiac output at presentation. Treatment is usually supportive, with avoidance of inotropes, which could exacerbate the systolic obstruction.

Mothers with anti-Ro or anti-La antibodies because of lupus erythematosus have a small (about 5%) but important risk for fetal heart block (see Chapter 18).[4] There is transplacental passage of immunoglobulin G antibody, with antibody and complement deposition in the fetal myocardium. The risk is not related to the severity of the maternal disease, and the diagnosis of the maternal collagen vascular disease could be prompted by the observation of fetal conduction abnormalities. Fetal conduction defects worsen during gestation and in the early years of life.[4] In utero symptoms are rare; however, when they are present, such as hydrops fetalis, congestive heart failure could be related to both decreased heart rate and myocardial inflammation.

Maternal treatment with dexamethasone in an attempt to reduce potential inflammation in the fetal myocardium and conduction system does not appear to be effective in reversing established rhythm abnormalities.[5] Careful postnatal follow-up is important for assessing symptoms and the ventricular rate. Temporary or permanent pacing might be advantageous even in the neonatal period if the ventricular rate is slow (less than 60 beats per minute) or there is feeding intolerance, and many children require permanent pacemakers early in life.[4] Cardiomyopathy might be present in the newborn period or could develop over the first months of life in these babies.[33]

Neonatal diagnosis has improved the prognosis of phenylketonuria in children. Women who have benefited from dietary therapy are reaching childbearing age, and poor control of the maternal disease during cardiogenesis is associated with a high risk for congenital heart defects.[28]

INFLUENCE OF GENETICS, SEX, AND RACE

Multiple epidemiologic studies suggest a multifactorial cause of congenital heart disease with a relatively low (3% to 5%) risk for recurrence in siblings or offspring of parents with congenital heart defects.[3] In some families, left heart defects or conotruncal defects might be under much greater genetic control.[16] Genetic analysis of these families, especially those with several affected members, will provide insight into the pathogenesis of congenital heart disease. Aortic stenosis and transposition of the great arteries are more common (65%) in male patients. Racial differences in the prevalence or type of congenital heart defects are surprisingly few.[10] The exception is the large percentage of supracristal ventricular septal defects in Japanese people. A group of Amish infants have been described with a lethal form of neonatal hypertrophic cardiomyopathy and found to be homozygous for a mutation in the myosin binding protein C3 (*MYBPC3*) gene, which has been associated in its heterozygous form with adult-onset hypertrophic cardiomyopathy.[38]

MAJOR ASSOCIATED NONCARDIAC DEFECTS

Two major associations, VACTERL and CHARGE, highlight the spectrum of associated defects observed in neonates with congenital heart defects. Although neither VACTERL nor CHARGE is caused by a single pathogenetic mechanism, recognition of these associations is helpful in facilitating multidisciplinary care and diagnosing all components of the association.

The VACTERL association describes a coincidence of defects, including vertebral abnormalities, anal atresia, tracheoesophageal fistula, renal abnormalities, congenital heart disease, and limb abnormalities. Seventy percent of infants with VACTERL have three affected systems, 25% have four components, and 10% have five components. The variability of the individual components is great, and congenital heart disease is present in about three fourths of infants with the VACTERL association. Ventricular septal defect, tetralogy of Fallot, and coarctation of the aorta are the most common defects. Vertebral abnormalities include hemivertebrae, hypoplastic vertebrae, and extra vertebrae. The vertebral abnormalities are often associated with rib abnormalities. Renal abnormalities, including fistula and urethral obstruction, are particularly important in neonates who also have anal atresia. Limb defects might be unilateral or bilateral and could include displaced or absent thumbs and radial abnormalities.

CHARGE is the association of *c*olobomas, *h*eart defects, choanal *a*tresia, growth and developmental *r*estriction, genital hypoplasia, and *e*ar abnormalities.[37] There is at least a 50% incidence of congenital heart defects in CHARGE association patients, with a preponderance of tetralogy of Fallot defects, including tetralogy of Fallot, tetralogy of Fallot with atrioventricular septal defect, tetralogy of Fallot with pulmonary atresia, and tetralogy of Fallot with Ebstein anomaly. Atrioventricular canal defects, double-outlet right ventricle, double-inlet left ventricle, and transposition of the great arteries have also been reported.

PART 4

Fetal Cardiac Physiology and Fetal Cardiovascular Assessment

Francine Erenberg

PHYSIOLOGY

The physiology of congenital heart disease is best understood in the context of understanding fetal blood flow patterns and the subsequent transition to a postnatal circulation.[21] Most significant cardiac lesions diagnosed in the newborn period are compatible with a relatively normal intrauterine existence. It is the transition to extrauterine life that makes most cardiac lesions hemodynamically significant.

As described in more detail later, in the fetal circulation, very little blood flow is required to go to the lungs because the placenta provides fetal oxygenation, and both ventricles are responsible for perfusing the systemic circulation. Many critical newborn lesions involve severely diminished pulmonary blood flow (e.g., pulmonary atresia, tricuspid atresia) and, therefore, are well tolerated in utero when this is the norm, but they become clinically significant in the neonate. Similarly, defects involving a single ventricle or large ventricular septal defect with mixing of right and left ventricular blood are well tolerated during fetal life when both ventricles normally act as "systemic ventricles." Finally, because the right ventricle also contributes to the perfusion of the aorta and systemic circulatory system, even lesions of severe left heart obstruction (e.g., interrupted aortic arch, hypoplastic left heart syndrome) can be well tolerated in the fetus.

After birth, however, closure of the ductus arteriosus results in inadequate pulmonary or systemic blood flow, leading to rapid demise if no intervention is undertaken. In many such infants, early management has as its goal the return of the circulation to the in utero situation for a period long enough to reach a diagnosis and begin definitive therapy.

Fetal Circulation

Circulation in the normal fetus differs from that of the normal newborn because of the following in utero characteristics:

- There is high pulmonary vascular resistance and low systemic vascular resistance.
- Right and left ventricles contribute to systemic perfusion and circulation.
- Additional structures are present: foramen ovale, ductus arteriosus, and ductus venosus.
- The placenta is the site of gas exchange for the fetus.

As opposed to that found in the child or adult, vasoconstriction of the pulmonary arteriolar bed maintains high resistance in the pulmonary circuit; this directs most of the right ventricular blood across the ductus arteriosus and into the descending aorta rather than to the branch pulmonary arteries and lungs. The right ventricle therefore provides blood to the descending aorta and the placenta through the ductus arteriosus. The left ventricle supplies the ascending aorta and the upper portion of the body, including the brain, and sends a small amount down the descending aorta to mix with the right ventricular output. Therefore, the two ventricles are essentially pumping in parallel, not in series, and there is a functional, but not absolute, separation in the systemic circulation in the fetus. From this separation, the right ventricle supplies the lower portion of the body, and the placenta and the left ventricle supply the upper portion of the body.

Oxygenation occurs in the placenta, and blood of higher oxygen content passes from the placenta into the umbilical vein. Umbilical venous blood is distributed to both lobes of the liver, whereas portal venous blood is distributed almost completely to the right lobe of the liver. About half of the umbilical vein blood bypasses the ductus venosus and enters directly into the inferior vena cava. Thus, inferior vena cava blood in the fetus contains relatively more oxygen. In contrast, superior vena cava blood is highly deoxygenated because it is the venous return from the head and upper body, and it has no admixture of oxygen-rich blood from the placenta.

Although both superior and inferior caval blood arrive in the right atrium, patterns of streaming within the right atrium continue to separate the blood in terms of oxygen content. Blood from the superior vena cava, which is low in oxygen content, preferentially crosses the tricuspid valve and is sent by the right ventricle, through the ductus arteriosus, to the descending aorta and placenta (where it is oxygenated). Blood from the inferior vena cava, which is higher in oxygen content because of the contribution from the placenta, preferentially crosses the foramen ovale to fill the left atrium and left ventricle; from there, it is sent predominantly to the upper portion of the body, the brain, and the coronary circulation. Thus, blood in the ascending aorta has more oxygen than that in the descending aorta, resulting in the brain receiving blood with a higher oxygen content than does the lower body and placenta.

Transition to Extrauterine Circulation

With birth, a number of important events take place that result in important physiologic changes to the newborn infant circulation. These changes include the following:

- Increase in the systemic vascular resistance
- Decrease in the pulmonary vascular resistance
- Closure of the ductus arteriosus and ductus venosus
- Transition to left-to-right shunting through the foramen ovale
- Eventual closure of the foramen ovale

Occlusion of the umbilical cord removes the low-resistance capillary bed from the systemic circulation, thus increasing the systemic vascular resistance of the infant. Breathing is followed by a marked fall in pulmonary vascular resistance.

The fall in pulmonary vascular resistance results in increased pulmonary venous return to fill the left atrium. The increased left atrial filling then limits and eventually eliminates flow from the inferior vena cava through the foramen ovale into the left atrium. The increased filling and pressure in the left atrium direct blood left to right across the atrial septum, eventually functionally closing the foramen ovale flap. Because blood that returns from the lungs is more completely oxygenated than the blood that was provided by the placenta, arterial oxygen saturation in the left heart (and thus the body) then increases, and the baby becomes pink.

There is loss of endogenous prostaglandins produced by the placenta. The increase in arterial oxygen saturation of the blood primarily brings about closure of the ductus arteriosus and ductus venosus. Most of the transition from fetal to neonatal circulation takes place in the first several minutes of life and is due to changes in vascular resistance. Functional closure of the ductus arteriosus takes place within 10 to 15 hours after birth, but anatomic closure occurs only within days to 2 weeks. The foramen ovale typically remains patent, with little to no flow through it for weeks or months, and in fact could remain patent into adulthood.

Pulmonary Vascular Bed

The pulmonary vascular bed is a key component in the pathophysiology of congenital heart disease, affecting its presentation and management. Thus, special attention is paid to the pulmonary vascular bed during neonatal life. The first breath is accompanied by a sudden and dramatic fall in pulmonary vascular resistance, and a further decrease in resistance occurs within the first several days of life as pulmonary arterioles relax and subsequently mature. In normal infants, the pulmonary vascular bed resembles the adult pattern, both in resistance and in histologic appearance, by several weeks of age. In some infants, however, this maturation of the pulmonary vascular bed does not occur, or it occurs over a longer period.

Two factors could be responsible for this difference. First, alveolar hypoxemia can maintain pulmonary vasoconstriction after birth, as in infants born at high altitudes and those with lung disease.[45] Second, primary or secondary changes in the pulmonary vasculature can result in persistent or recurrent increase in arteriolar tension, resulting in pulmonary hypertension. Secondary pulmonary hypertension is much more common and could be a result of severe, persistent intrinsic lung disease or hypercarbia, as in a child with severe bronchopulmonary dysplasia, or it could be a result of congenital heart disease. An example of the latter is an infant with a large left-to-right shunt, such as a large ventricular septal defect. In this instance, the presence of the defect allows transmission of systemic left ventricular systolic pressure to the right ventricle and in turn to the pulmonary artery and pulmonary vascular bed.

This pulmonary hypertension interferes with the normal fall in pulmonary resistance described earlier, and the resistance could stay high until 1 or 2 months of age. In some patients with very large left-to-right shunts, often with the combination of excessive pulmonary blood flow, pulmonary resistance never falls, or after briefly falling, it becomes secondarily elevated again. Defects of this type, if not corrected surgically, eventually result in irreversible pulmonary vascular disease, or Eisenmenger syndrome.

CARDIOVASCULAR ASSESSMENT

Fetal cardiology is a field that requires the combined expertise of the pediatric cardiologist, the perinatal obstetrician, the geneticist, and the neonatologist. The main tool in fetal cardiac assessment is the fetal two-dimensional echocardiogram and Doppler examination, which is used in the diagnosis and follow-up of fetuses with structural congenital heart disease, arrhythmia, and myocardial disease or congestive heart failure. Fetal three- and four-dimensional echocardiography is also used to expand some of the diagnostic ability and precision of the two-dimensional scan.[39,56] Fetal electrocardiography, fetal magnetocardiography, and fetal cardiac magnetic resonance imaging are other techniques used, but these continue to have limitations and are generally used only in selected clinical scenarios or centers and not as screening or routine tools.

Fetal electrocardiography using maternal abdominal electrodes has been attempted, but with little success because of several limitations. These limitations include the insulating effect of the vernix caseosa after 27 weeks' gestation, the lack of consistent positioning of the fetus within the maternal abdomen, and the preferred conduction pathways between the fetal heart and maternal abdomen after about 27 weeks' gestation.[57] Fetal magnetocardiography has been used in attempts to increase the sensitivity of fetal heart rate tracings in the assessment of fetal well-being and in the diagnosis of arrhythmias. Its current role remains extremely limited because it is time consuming, expensive, and available only at a few centers.[47]

In addition to identifying specific lesions, fetal echocardiography can be used to aid our understanding of the physiology and natural history of conditions throughout pregnancy and for monitoring the heart during cardiac and noncardiac fetal interventions.

Indications for Fetal Cardiovascular Assessment

The incidence of congenital heart disease in the general population is about 1 per 125 live births.[2] The incidence in fetal life is actually higher because of fetal wastage from the heart defects, associated aneuploidy, or other congenital defects. A detailed fetal echocardiogram is both time intensive and labor intensive; for this reason, its use has been directed toward those pregnancies considered at increased risk for having a fetus with congenital heart disease. These include a family history of congenital heart disease in one of the parents or a previous sibling. Compared with the baseline risk, a family history raises the risk for fetal heart defects from 0.5 to 1 per 100 in the general population to 3 to 14 per 100.[41] Given this incremental risk, it is considered an important indication for fetal screening.

High-risk groups can further be divided into those with increased maternal risks and those with increased fetal risk factors.[10,44] These risk factors are listed in Box 45-1.

Certain extracardiac malformations have an especially high association with congenital heart disease. These include omphalocele (30%), diaphragmatic hernia, duodenal atresia, single umbilical artery, tracheoesophageal fistula, cystic hygroma, and increased nuchal translucency. Increased nuchal translucency is often seen in trisomy 21 or other chromosome abnormalities; in this context, the association with congenital heart defects is as high as 90%. Even in the absence of abnormal karyotype, increased nuchal translucency has a significant association with congenital heart disease, especially with increasing levels of edema.[24] Newer work suggests that increased nuchal translucency is not an appropriate screening test for congenital heart defects, but that the finding of increased nuchal translucency on screening ultrasound demands a formal fetal echocardiogram and more thorough evaluation for the presence of a structural heart defect.[35,55,63]

Box 45-2 lists indications for performing echocardiography in the fetus.

Finally, referrals sent secondary to suspected abnormality from a screening obstetric ultrasound have the highest yield; at least half of all mothers referred for detailed fetal cardiac studies on this basis are found to have fetuses with cardiac abnormalities.[1,8] The yield may be even higher depending on the skill level of the referring center. However, it should be noted that recent data from California indicate that overall prenatal detection of major congenital heart disease only occurs in less than 50% of cases.[20] In other series, the numbers range from 57% to 65%. To identify most lesions that can occur in the fetus, in addition to the traditional four-chamber view, it is necessary to include a view of the outflow tract using the most sophisticated equipment and have highly trained operators.[14]

BOX 45–1 Risk Factors for Congenital Heart Disease

MATERNAL RISK FACTORS

- Maternal metabolic disorders (diabetes, phenylketonuria)
- Exposure to known teratogen (viral or drug), especially earlier than 8 weeks of gestation
- Maternal autoantibodies (fetal heart block)
- Maternal congenital heart disease: 5% to 10% recurrence risk, depending on lesion

FETAL RISK FACTORS

- Suspicion of congenital heart disease on obstetric ultrasound
- Extracardiac malformations or major anomalies of other organ systems
- Aneuploidy or abnormal karyotype
- Increased nuchal thickening, even in the absence of abnormal karyotype
- Arrhythmia
- Fetal hydrops, about 25% of which is cardiac

BOX 45–2 Indications for Fetal Echocardiography

- Abnormal screening obstetric ultrasound
- Fetal arrhythmia
- Family history of congenital heart disease
- Maternal diabetes
- Maternal teratogen exposure (first trimester)
- Extracardiac anomalies
- Aneuploidy or abnormal karyotype
- Hydrops fetalis
- Increased nuchal translucency

Timing

The ideal timing of screening for fetal congenital heart defects is a compromise between obtaining adequate images for diagnosis in most routine patients and yet offering diagnosis as early as possible for parents to consider all options, including termination of pregnancy, if applicable.[38] Scanning must, therefore, occur sufficiently late to have adequate anatomic assessment and not miss late-developing lesions, and it must be early enough for all pregnancy outcomes to be considered. For the low-risk patient, this window is generally about 20 weeks of gestation. For those at high risk, such as fetuses with significant nuchal translucency or a family history, especially of left heart obstructive lesions, a preliminary examination at 11 to 15 weeks by transabdominal or transabdominal plus transvaginal echocardiogram should be considered and has been shown to have reasonable accuracy. Studies performed in the late first trimester are generally followed up with a more detailed study at 18 to 20 weeks' gestation.[3,25] In one series, 160 fetal echocardiograms were performed at a mean gestational age of 13.5 weeks in a population at high risk for anomalies. Twenty cardiac defects were found in this cohort, 14 of which were identified at the early echocardiogram, and 6 which were identified at the later study.[4]

Methods

Despite newer techniques, the two-dimensional and Doppler fetal echocardiogram remains the mainstay of fetal diagnosis, often supplemented with newer techniques targeted to provide additional anatomic or functional information. Studies are generally performed at 18 to 20 weeks' gestational age, although transabdominal, and certainly transvaginal, imaging can be performed as early as 11 weeks.

Adequate images can be obtained in nearly all pregnancies, although maternal obesity can limit the studies. The standard examination uses the approach known as *segmental anatomy*, the same method used in the pediatric echocardiogram, and consists of several views. The goal of the segmental anatomy approach is to scan from multiple standard views to assess the heart in terms of its segments, specifically the venous-atrial connections, the atrioventricular (AV) connections, and the ventriculoarterial connections, on both the right and left side of the heart. The basic anatomy is thus visualized by the two-dimensional component of the echocardiogram and is composed of a series of views aimed at assessing the various structures and their anatomic relationships.[3]

Fetal echocardiography is performed both by perinatologists and pediatric cardiologists, and sometimes jointly, as a collaborative effort. The ongoing assessment of the fetus is necessarily a collaborative effort between the two, with the perinatologist able to provide expertise during the antenatal period, and the pediatric cardiologist able to provide to the patient appropriate counseling and background regarding the congenital cardiac defect, the expected or possible postnatal courses, and the natural history of the abnormalities. As the field of antenatal cardiac imaging has developed, there has been interest in standardizing the tool. Recommendations have been made by several organizations to provide guidelines and consensus in this area.[31,49]

In addition to the two-dimensional imaging, pulsed and continuous-wave Doppler and color flow mapping permit evaluation of normal and abnormal flow patterns. These studies are useful for assessing for valvular stenoses, ventricular septal defects, and particularly left heart obstructive lesions, where the flow across the foramen ovale becomes left to right (due to the left heart obstruction), instead of the right-to-left flow seen in the normal fetus. Additional tools potentially useful in the fetal cardiac assessment are the three-dimensional fetal heart assessment and the three- and four-dimensional color Doppler using spatiotemporal image correlation. This is an automated procedure whereby a volume of data is acquired from the fetal heart, which includes both gray-scale three-dimensional images and color Doppler. The information is then presented in multiple planes, which can be evaluated without significant postprocessing. Limitations remain with this technique that are largely technical, including low discrimination of signal, especially early in gestation.[13] These newer techniques have been shown to add some level of detail but are probably only marginally additive to a thorough two-dimensional and Doppler echocardiogram performed by an expert.[26,62]

Cardiac size, growth, and ventricular function can also be assessed by the echocardiogram, and serial examinations can be used to compare interval change in size and function. In addition to the data typically obtained in an anatomic survey, various modalities exist to quantitatively assess the heart size and function in situations of fetal congestive heart failure. These include the comparisons of the cardiac to thoracic area or circumference, which are expressed as a ratio[48] (Fig. 45-7). Assessment of actual cardiac function can be undertaken in the fetus using techniques such as cardiac output or shortening fraction of both ventricles. Methods aimed at assessing overall cardiac performance include the Doppler-derived Tei index,[60] used in the fetus on both the right and left ventricles,[22] and a cardiovascular profile scoring system has been proposed that combines assessment of cardiac function with assessment for abnormality in venous and arterial Doppler pulsations, heart size, and evidence of hydrops.[17]

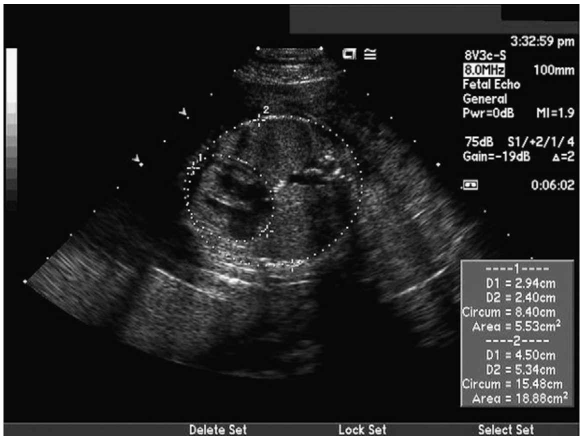

Figure 45–7. Two-dimensional fetal echocardiogram showing measurement of the fetal heart (1) and thorax (2) circumferences, used in calculating the cardiac-to-thoracic ratio.

Finally, fetal arrhythmias can be extensively investigated by comparing the timing of atrial and ventricular wall motion from M-mode recordings or from the Doppler flow patterns across the mitral and aortic valves.

Recognition of Fetal Cardiac Abnormalities

CONGENITAL HEART DEFECTS

Despite significant advances in fetal imaging, most congenital heart disease remains undetected until after birth. Well over one third of cases occur in pregnancies not otherwise identified as high risk.[15,59] For this reason, prenatal detection of congenital heart disease relies heavily on the screening fetal ultrasound. For many years, therefore, incorporation of a four-chamber view of the heart into formal guidelines for the screening fetal ultrasound has existed.

Most significant cardiac defects are excluded by a normal four-chamber view, but those not resulting in ventricular hypoplasia and those predominantly involving abnormalities of the outflow tracts will still be missed. Therefore, there has been interest in including outflow tract visualization in the standard screening fetal ultrasound. This appears to have an incremental value in the detection rate of congenital heart defects from 50% to as high as 85% to 90%.[11,28] Defects not detected with this screening tend toward those not requiring neonatal intervention. False-positive findings are also possible, and they often involve coarctation of the aorta or small ventricular septal defects.[8,42]

Defects associated with hypoplasia of the right or left ventricle are easily identified on the four-chamber view. Similarly, abnormal size of the aorta or pulmonary artery caused by semilunar valve stenosis or diminished arterial flow is readily seen. Milder degrees of aortic or pulmonary stenosis can be difficult to identify if they are not associated with abnormal arterial size or dramatic valve deformity. Large ventricular septal defects are easily identified, particularly when associated with tetralogy of Fallot or with AV septal defects. Greater difficulty is encountered in trying to identify small or medium-sized ventricular septal defects.[5] For this reason, there is a skew toward the fetal diagnosis of more complex forms of congenital heart disease compared with the general distribution of defects. This, coupled with fetal wastage due to the cardiac (or more often the associated noncardiac) genetic or somatic defects, results in a worsened natural history for congenital heart disease diagnosed prenatally compared with patients whose heart disease is diagnosed after birth.

Abnormalities of the superior vena cava or the inferior vena cava, such as an interrupted inferior vena cava with azygous continuation, are readily seen, and they are often noted because of their association with complex problems such as the heterotaxy syndromes. Color flow Doppler mapping has improved the ability to document pulmonary venous flow into the left atrium, improving the prenatal diagnosis of abnormalities of pulmonary venous connection. Pulsed Doppler recordings of the pulmonary veins are useful in assessing obstruction of the foramen ovale in fetuses with hypoplastic left heart syndrome.[6,27]

Structures that are normal in the fetus but abnormal in postnatal life cannot be diagnosed antenatally. Coarctation of the aorta can be challenging to identify because it might not become obstructive until the ductus arteriosus closes. More severe forms of coarctation are usually associated with varying degrees of transverse arch hypoplasia and are less likely to be overlooked.[27,51]

ARRHYTHMIAS

Intermittent premature atrial or ventricular contractions are often noted during fetal echocardiography.[58] They are rarely predictive of more complex arrhythmias, and they share the same benign prognosis as they do in the infant. Sustained fetal arrhythmias can be divided into tachyarrhythmias and bradyarrhythmias, as in the neonate or child.

Fetal tachyarrhythmias are much more common than bradyarrhythmias. Fetal AV reentry tachycardia, atrial tachycardia, or flutter[33] is usually easily differentiated from the rare fetal ventricular tachycardia[29] by the timing of atrial and ventricular wall motion on M-mode echocardiography (Fig. 45-8). Intermittent atrial tachycardia, or that at a relatively low rate (<190 beats per minute) is usually well tolerated.[54] Sustained fetal tachycardia, however, especially when it occurs in midgestation, is poorly tolerated and often leads to fetal hydrops[40] (Fig. 45-9).

Fetal bradycardia is usually due to complete heart block or conduction abnormalities. This is most commonly associated with maternal autoantibodies (anti-SSA, anti-SSB) or with congenital heart disease, especially complex AV septal defects, heterotaxy syndrome, and ventricular inversion.[9] Isolated complete heart block is usually well tolerated in utero, as opposed to complete heart block associated with congenital heart disease, which has a grave prognosis for development of hydrops and fetal demise.[9]

FETAL CONGESTIVE HEART FAILURE AND MYOCARDIAL DISEASE

The cardiac physiology of the fetus allows adaptation to many of the cardiac defects that cause significant problems after birth. Specifically, postnatal congestive heart failure caused by significant left-to-right intracardiac shunting and pulmonary overcirculation is not expressed in the fetus. Congestive heart failure in the fetus, conversely, is generally caused either by myocardial dysfunction or severe regurgitation of the AV valves. Such lesions are poorly tolerated by the fetus, and this type of congestive heart failure often results in hydrops fetalis. Types of hydrops fetalis related to cardiovascular function are listed in Box 45-3.

Regurgitation from the AV valves of the right or left ventricle produces a significant fetal volume load that is not well tolerated. Lesions in which this is seen include Ebstein anomaly of the tricuspid valve,[45] pulmonary atresia with intact ventricular septum, AV septal defects with severe AV valve regurgitation,[53] and severe tricuspid insufficiency seen in the recipient twin in twin-to-twin transfusion syndrome.[46] In most fetuses with critical aortic stenosis, the left ventricle is simply bypassed, and the systemic circulation is perfused with the right ventricle through the ductus arteriosus, but severe left ventricular dilation and dysfunction, with mitral regurgitation, can develop.[52]

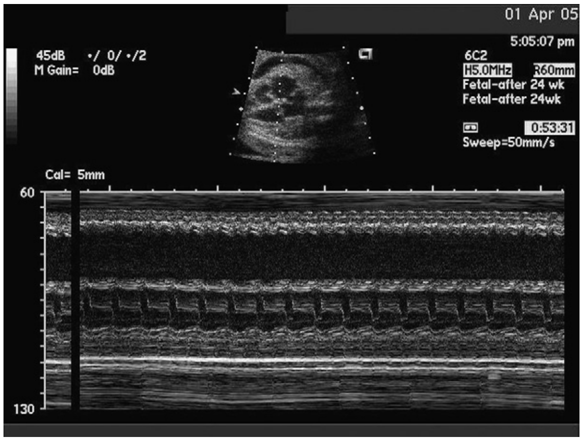

Figure 45–8. M-mode fetal scan through the atrial and ventricular walls, demonstrating atrial flutter. The atrial wall motion (*top of frame*) is twice that of the ventricular wall motion (*bottom of frame*).

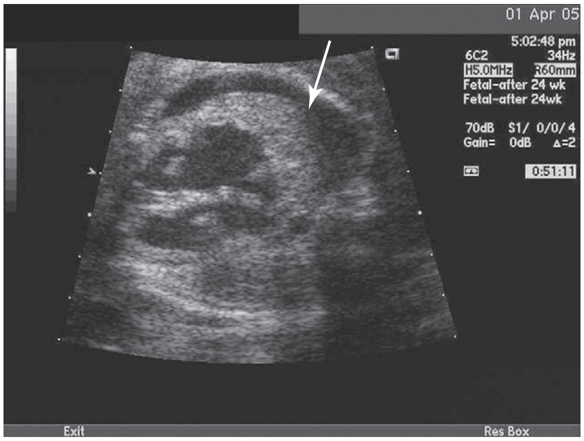

Figure 45–9. Two-dimensional fetal echocardiogram showing a four-chamber fetal heart with a large pleural effusion (*arrow*). The fetus had sustained tachycardia.

BOX 45–3 Nonimmune Hydrops Fetalis Related to Cardiovascular Function

ATRIOVENTRICULAR OR SEMILUNAR VALVE REGURGITATION
Atrioventricular canal defect
Ebstein anomaly or tricuspid valve dysplasia
Absent pulmonary valve syndrome

CRITICAL AORTIC STENOSIS

ARRHYTHMIAS
Supraventricular tachycardia
Atrial flutter
Complete atrioventricular block
Sinus or junctional bradycardia

MYOCARDIAL DISEASE
Myocarditis
Myocardial infarction
Cardiomyopathy

MISCELLANEOUS
Premature closure of the ductus arteriosus
Arteriovenous fistulas
Severe anemia

Conditions that affect myocardial function, such as viral myocarditis and intrauterine myocardial infarction, can severely compromise cardiac output and cause congestive heart failure in utero. Similarly, fetal cardiomyopathies are a rare and heterogeneous group of lesions that can even evolve throughout the pregnancy or beyond.[46] Premature closure of the ductus arteriosus can result in severe right ventricular pressure overload as the right ventricle becomes unable to unload its output to either the pulmonary or systemic circulations. Maternal indomethacin therapy, for example for preterm labor, is known to be associated with premature closure of the ductus arteriosus.[32] Women receiving this treatment during gestation are generally followed closely, with attention paid to the patency of the ductus arteriosus, development of tricuspid insufficiency, and development of fetal congestive heart failure.

Arrhythmias are also an important cause of fetal congestive heart failure. Bradyarrhythmias caused by complete heart block, especially when associated with structural lesions such as L-transposition of the great arteries, heterotaxia, or AV septal defects, can lead to fetal congestive heart failure. Fetal heart rates less than 55 beats per minute are usually poorly tolerated by the fetus. The fetus might also poorly tolerate tachyarrhythmias, such as persistent supraventricular tachycardia or atrial flutter. Finally, noncardiac causes of congestive heart failure in utero, such as arteriovenous fistulas, large sacrococcygeal teratomas, and severe anemia, should be considered.

Treatment

Most congenital heart disease can now be repaired safely in infancy with excellent surgical survival and good long-term prognosis. For these defects, therefore, there would be no need for fetal intervention. In utero intervention has been limited to those disease states that lead either to in utero demise (largely fetal arrhythmias) or to palliative procedures in defects that might be progressive during fetal life, and theoretically improved outcome could therefore be expected if intervention is undertaken earlier. The latter has largely been an experience with fetal intervention for aortic or pulmonary valve stenoses, with the ultimate goal of limiting progression to ventricular hypoplasia. Technical success for the procedure has been achieved at several centers worldwide.[30,37] The ultimate question of whether progression of ventricular hypoplasia can be halted remains guarded; recent analyses, however, have assessed technical aspects of the procedures, including patient selection and technique, with an eye toward increasing the success rate.[36] Large pericardial effusions have also been drained successfully in utero (see also Chapter 11).

As opposed to in utero intervention for structural congenital heart defects, antenatal management of fetal arrhythmias has the longest history and greatest success for fetal cardiovascular therapy. Tachyarrhythmias, particularly supraventricular tachycardia, have been successfully controlled by maternal administration of antiarrhythmic medications. Indications for treatment of fetal arrhythmias are still not clearly defined, but single ectopic beats and short, nonsustained runs of tachycardia do not appear to be associated with morbidity. Sustained tachycardia at rates greater than 200 beats per minute may lead to hydrops and ultimately to fetal demise and is a generally accepted indication for fetal therapy.

Digoxin remains a first-line drug at many institutions, although many drugs have been used, including flecainide,[23] verapamil, propranolol, sotalol,[43] and amiodarone.[54,58] Nonhydropic fetuses have a high success rate for transplacental treatment, although fetuses presenting with hydrops have a worse prognosis, with 27% mortality in one series.[54] In severe fetal hydrops, direct administration of drugs by umbilical vein puncture improves drug delivery but clearly has higher risk to the fetus. For fetal bradycardia, maternal steroids have been administered for treatment of fetal heart block caused by maternal lupus erythematosus.[50] Early treatment of an affected fetus can improve or prevent the loss of AV nodal conduction (complete heart block).

Outcome

With the exception of cases of large pericardial effusion with tamponade, balloon valvuloplasty of the aortic valve, and treatment of sustained arrhythmia, the prenatal diagnosis of congenital heart disease generally does not result in direct intervention to the fetus. This is not to say that the impact of a prenatal diagnosis of a congenital heart defect does not affect the pregnancy; it is likely to have an important role in terms of parental counseling, decisions regarding termination of pregnancy, perinatal planning, and fetal outcome.

Outcome studies regarding the impact of fetal echocardiography and fetal cardiac diagnosis have been performed. Many assess individual defects, including hypoplastic left heart syndrome,[7,34] truncus arteriosus,[16] AV septal defects,[19] and aortic stenosis. Initial reviews comparing the natural history for groups of fetuses with congenital heart defects diagnosed prenatally and those of children with defects diagnosed after birth show a worse outcome as a group for those with prenatal diagnosis.[18] These findings are attributable to the higher detection rate of complex defects (versus simple defects) before birth, the increasing severity of lesions detected prenatally compared with postnatally, and the higher association of prenatal heart defects with extracardiac anomalies that can add to their morbidity.

Direct comparisons of cohorts of infants with fetal versus postnatal diagnosis of complex congenital heart defects have shown improved outcome of children with defects diagnosed prenatally, however. Several series of infants with hypoplastic left heart syndrome, severe left heart obstructive lesions, and transposition of the great arteries have shown significantly less metabolic acidosis in infants with prenatal diagnosis as opposed to those with postnatal diagnosis.[12,61] A large, single-center study has already shown improved neurologic outcome and less metabolic acidosis in infants with prenatal diagnosis.[34] Future studies are needed to assess the relationship of improved perinatal management strategies on the ultimate outcome.

PART 5

Principles of Neonatal Cardiovascular Hemodynamics

Kenneth G. Zahka

The following pathophysiologic principles provide the background needed for understanding the consequences of the transition from fetal to newborn life with normal and abnormal cardiac development. These principles are essential to an understanding of cardiac catheterization data and are integral to the clinical care of neonates with congenital heart disease.[7]

PRESSURE, FLOW, AND RESISTANCE

The pressure (P) in a chamber or vessel is related to the blood flow ($\dot{Q}$) and the resistance (R):

$$\Delta P = \dot{Q} \times R$$

or

$$\frac{\Delta P}{\dot{Q}} = R$$

Pressure is measured directly by catheterization or by sphygmomanometry. In neonates, flow is measured from oxygen data or thermodilution in the cardiac catheterization laboratory. It can also be estimated from noninvasive echocardiography and Doppler data. Resistance is always calculated from pressure and flow data.

The most basic application of this principle is the calculation of systemic and pulmonary vascular resistance. Resistance is directly related to the pressure drop across the vascular bed (ΔP, or the mean arterial pressure minus the mean atrial pressure) and inversely related to the blood flow. In the neonate, the normal postnatal fall in pulmonary artery pressure might be explained by a drop in left atrial pressure, a fall in pulmonary blood flow, or a decrease in the resistance to blood flow through the lungs. Clearly, on the basis of known data, the decrease in resistance is the only plausible factor.

In a neonate with high pulmonary artery pressure and a congenital heart defect, it is essential to know whether the high pulmonary artery pressure is due to high flow with low resistance or to normal flow with high resistance. Measurement of pressure and flow with calculation of resistance directs logical therapy in these infants. If the pressure is elevated because of increased flow with normal resistance, treatment to lower the resistance will likely only increase the flow and make the infant's condition worse.

This principle also explains the minimal pressure gradients across the aortic valve in critical aortic stenosis and left ventricular failure. If the resistance is high (in this case, the aortic valve) and the flow is low (poor cardiac output caused by left ventricular failure), the pressure drop across the valve will be small. Opening the valve (lowering the resistance) and improving left ventricular function (increasing flow) usually increase the pressure gradient (ΔP) in these infants.

MEASUREMENT OF BLOOD FLOW

Blood flow (systemic, $\dot{Q}s$; pulmonary, $\dot{Q}p$) can be estimated from the oxygen consumption and the arteriovenous oxygen difference with the Fick principle:

$$\dot{Q}s = \frac{\dot{V}O_2}{[(\text{Ao sat} - \text{SVC sat}) \times 13.6 \times (\text{g Hb/dL})]}$$

$$\dot{Q}p = \frac{\dot{V}O_2}{[(\text{PV sat} - \text{PA sat}) \times 13.6 \times (\text{g Hb/dL})]}$$

where oxygen consumption ($\dot{V}O_2$) is in milliliters per minute; aortic (Ao), superior vena caval (SVC), pulmonary venous (PV), and pulmonary arterial (PA) oxygen saturations (sat) are expressed as decimals (e.g., 98% = 0.98); and oxygen capacity (in milliliters per liter) is 13.6 times the hemoglobin concentration in grams of hemoglobin per deciliter.

Oxygen saturation is measured by hemoximetry or is calculated from a blood gas measurement. If the infant is receiving supplemental oxygen, then dissolved oxygen might not be trivial (PO_2 = 0.03 mL/mm Hg) compared with bound oxygen, and it must be included in the calculation of oxygen content:

$$\text{Oxygen content} = \text{sat} \times 13.6 \times \text{Hb concentration} + 0.03\text{ mL} \times PO_2$$

where oxygen content is measured in milliliters per liter and hemoglobin concentration in grams per deciliter. In this case, systemic and pulmonary blood flow can be calculated as follows:

$$\dot{Q}s = \frac{\dot{V}O_2}{(\text{Ao content} - \text{SVC content})}$$

$$\dot{Q}p = \frac{\dot{V}O_2}{(\text{PV content} - \text{PA content})}$$

where Ao content, SVC content, PV content, and PA content are derived from the oxygen content equation. The Fick principle provides a convenient and reliable means of measuring blood flow in the cardiac catheterization laboratory or intensive care unit with appropriate vascular access to obtain the samples. It also gives excellent insight into the factors that have an impact on oxygen delivery and use.

Oxygen consumption varies with activity and metabolic state. In neonates, oxygen consumption can be measured by analysis of expired gas with a metabolic cart and use of the polarographic method. More typically, it is estimated from body surface area, 150 mL/m^2 per minute. Deviations from that assumed value because of activity or illness alter the calculated output, but it can also be seen that if oxygen consumption increases, the blood flow must increase, the arteriovenous difference must increase, or the oxygen content must increase. The neonate with adequate cardiovascular reserve increases blood flow. The infant with poor cardiac output must extract more oxygen, or an oxygen debt will develop in the tissues. The critical and therapeutic role of transfusion or oxygen therapy for the neonate with limited reserve can also be seen.

Thermodilution and dye dilution are techniques for measuring blood flow in older children but that require special adaptation for newborn infants. In both cases, a known amount of an indicator (cold or green dye) is injected into the circulation. Sampling (with a thermistor or photocell) is done distal to the injection site. The amount of dilution of the indicator is directly related to the blood flow between the injection and sampling sites. These techniques are most likely to be applicable to neonates with structurally normal hearts.

Estimation of flow by Doppler is integrated into all echocardiography machines:

$$\dot{Q} = \text{VTI} \times \text{CSA}$$

where VTI is the velocity time integral, or mean velocity, and CSA is the cross-sectional area of the vessel at that site calculated from the diameter. This calculation assumes laminar flow and is sensitive to accurate measurement of the diameter.

INTRACARDIAC SHUNTING

The location of a left-to-right or right-to-left shunt can be detected by an increase or decrease in the oxygen saturation at the atrial, ventricular, or arterial level. The magnitude of the shunt is indicated by a change in oxygen saturation.

This concept is an extension of principles outlined under "Measurement of Blood Flow," earlier. If there is no shunting, then pulmonary artery oxygen saturation must be the same as superior vena caval oxygen saturation. In practice, there is some variation in oxygen saturation throughout the right side of the heart because of differences in oxygen extraction by the head, liver, and other abdominal organs. Thus, it is useful to take multiple samples to identify the site of shunting and to avoid errors resulting from uneven mixing of venous flows. A change in saturation of 5% is likely to be significant.

The relative pulmonary and systemic blood flow can be estimated without measuring the $\dot{V}O_2$ or calculating oxygen capacity (13.6 × g Hb/dL):

$$\dot{Q}p/\dot{Q}s = (\text{Ao sat} - \text{SVC sat})/(\text{PV sat} - \text{PA sat})$$

This approach does not permit calculation of vascular resistance or flow, but it does give an estimate of relative pulmonary flow and systemic flow. For babies with a left-to-right shunt, $\dot{Q}p/\dot{Q}s$ of less than 1.5 is small, 1.5 to 2.5 is moderate, and greater than 2.5 is large. For newborn infants with a right-to-left shunt, $\dot{Q}p/\dot{Q}s$ of 0.9 to 1.0 is small, 0.7 to 0.9 is moderate, and less than 0.7 is large.

When two chambers or vessels are connected (e.g., ventricular septal defect), the flow through the connection is related to the size of the connection and the relative resistance to blood flow leaving the chamber or vessel (e.g., the aorta and the pulmonary artery). If the resistances are equal, no significant flow will cross the defect regardless of its size. If the defect is tiny, not much flow will cross the defect regardless of the relative systemic and pulmonary resistance.

This principle helps explain why a newborn infant with ventricular septal defect does not have a murmur in the delivery room when pulmonary vascular resistance is high. It also introduces the concept of a restrictive and a nonrestrictive defect. A nonrestrictive defect provides no resistance to flow and allows equalization of pressure between the two chambers. In contrast, small defects have resistance to flow and do not allow pressures to equalize.

CHAMBER AND VESSEL SIZE

Chamber and vessel size are proportional to the blood flow through them. Why do cardiac structures grow or dilate? Whether the consideration is the normal increase in cardiac output with growth or an increased flow resulting from congenital heart disease, the heart is sized relative to volume load. Important exceptions are if the wall is weak (e.g., the aorta in Marfan syndrome) or if the muscle is weak and the diastolic pressure is high (cardiomyopathy in the left ventricle, dilation of the left atrium because of mitral stenosis). If an echocardiogram or angiogram shows a dilated chamber, there must be an explanation based on this principle. The same is true for chambers that are smaller than normal.

WALL THICKNESS

Wall thickness (hypertrophy) develops in response to the factors that increase wall stress: the pressure in the chamber and the size of the chamber. Usually, hypertrophy occurs in an attempt to normalize wall stress. For this reason, with normal ventricular growth, the wall thickens in proportion to the chamber size. It is also the reason that left ventricular wall thickness is a good sign of the severity of aortic stenosis or systemic hypertension. Important exceptions are hypertrophic cardiomyopathy, in which the feedback to muscle mass is inappropriate, and infiltrative diseases.

ASSESSMENT AND DEVELOPMENTAL ASPECTS OF MYOCARDIAL PERFORMANCE

The characterization of ventricular function or myocardial performance has been the focus of decades of research, with the goal of defining myocardial contractility, afterload, and preload in the complex neurohumoral environment of the intact circulation. Superimposed on this challenge are the developmental changes in heart rate and the confounding factor of normal growth.[5]

Developmental Changes in Myocardial Structure

Myocyte number (hyperplasia) and size (hypertrophy) increase during maturation until shortly after birth, when only hypertrophy occurs.[9] Myofibrillar density and organization are lower in the immature myocardium. Only 30% of the fetal myocardial cell consists of myofibrils, in comparison with 60% in the adult myocardium. Ion channels and pumps, which regulate calcium, sodium, potassium, and hydrogen passage in the sarcolemma and T tubules, change from those in the fetus to those in the mature animal, although the impact on function is not clear. Mitochondrial size and complexity increase during development, and there is maturation of the energy-producing enzymes within the mitochondria. Fatty acid transport is deficient in the newborn infant's myocardium, and carbohydrate is the principal energy source.

Myofibrils are composed of a number of proteins, including myosins, actin, tropomyosins, and troponins. The isoforms of troponin T that are present in the fetal and neonatal myocardium appear to be less sensitive to calcium than those in the adult myocardium. Sarcoplasmic reticulum density and organization are decreased in the immature myocardium, which impairs calcium transport into the myofibrils. These developmental changes in myocardial structure, energy use, and ion transport likely have implications for the functional development of the myocardium from the fetus to the adult.[2]

Systolic Ventricular Function

PEAK DEVELOPED PRESSURE

The simplest measure of ventricular function is systolic blood pressure. Systolic pressure gradually increases in the fetus and during the first months of life, yet adult levels of blood pressure are not reached until late childhood (see Appendix B). Although blood pressure is useful because the clinician is able to integrate the imponderables of age, afterload, and preload, blood pressure as a measure of systolic function has limitations. A simple interpretation of that observation is that because the neonatal heart does not develop the same peak force as an adult heart, the immature myocardium is intrinsically functionally impaired compared with the mature myocardium. These observations do not account for the cross-sectional area of muscle mass, nor do they explain the ability to generate high pressures in response to obstruction.

STROKE VOLUME AND CARDIAC OUTPUT

The fetal circulation dictates a consideration of the combined ventricular output rather than separate right and left ventricular output.[12] Fetal cardiac output is sensitive to heart rate and is relatively insensitive to preload and afterload. After birth, there is a dramatic increase in left ventricular output[1] and a high level of endogenous β-adrenergic stimulation. This high level of β-adrenergic stimulation and the immaturity of myocardial calcium handling are in part responsible for the decreased contractile reserve of the neonate.

Cardiac output increases dramatically from the neonate to the adult. When the cardiac output is indexed for body surface area, which provides the cardiac index, normal neonatal left ventricular flow is between 4.0 and 6.5 L/m^2 per minute depending on the modality used to measure the output.

EJECTION FRACTION AND SHORTENING FRACTION

Ejection fraction (EF) and shortening fraction (SF) are measures of relative shortening of the myocardium during systole:

$$\mathrm{EF}(\%) = 100 \times \frac{(\mathrm{EDV} - \mathrm{ESV})}{\mathrm{EDV}}$$

$$\mathrm{SF}(\%) = 100 \times \frac{(\mathrm{EDD} - \mathrm{ESD})}{\mathrm{EDD}}$$

where EDV is end-diastolic volume, ESV is end-systolic volume, EDD is end-diastolic dimension, and ESD is end-systolic dimension. Each measurement is easily calculated from either angiography or echocardiography. Normal values (EF, 65% to 80%; SF, 28% to 40%) vary surprisingly little with age. Muscle shortening is afterload dependent, and acutely increasing the vascular resistance decreases the EF without necessarily changing intrinsic myocardial contractility.

VELOCITY OF CIRCUMFERENTIAL FIBER SHORTENING

Velocity of circumferential fiber shortening (VCF) is a measure of systolic function that indexes the SF by dividing the SF by the ventricular ejection time (VET):

$$\mathrm{VCF} = \frac{\mathrm{SF}}{\mathrm{VET}}$$

The VCF value (normal, 1.25 + 0.15 circumferences per second) does change with heart rate and can be rate corrected. Corrected VCF (VCFc; normal, 1.01 + 0.11 circumferences per second) is calculated by dividing the VCF by the square root of the R-R interval:

$$\mathrm{VCFc} = \frac{\mathrm{VCF}}{\sqrt{\mathrm{R} - \mathrm{R}}}$$

WALL STRESS

Wall stress (WS), or force per unit area, has been assumed to be constant during one's lifetime and reflects the law of Laplace, which states:

$$\mathrm{WS} = \mathrm{P} \times \frac{\mathrm{D}}{\mathrm{h}}$$

where P is pressure, D is dimension, and h is wall thickness at any given time in the cardiac cycle. Peak systolic wall stress is about 225 g/cm^2. In the infant with aortic stenosis, increased cavity pressure typically increases wall thickness, and during growth, an increase in chamber size and pressure is accompanied by an increase in wall thickness. End-systolic wall stress (ESWS) is the best estimate of afterload. ESWS (in grams per square centimeter) can be estimated by the following equation, with measurements of end-systolic pressure ($\mathrm{P_{es}}$) and dimension ($\mathrm{D_{es}}$) (end-systolic pressure must be estimated from a carotid pulse tracing and aortic pressure):

$$\mathrm{ESWS} = \frac{(1.35 \times \mathrm{D_{es}} \times \mathrm{P_{es}})}{4 \times \mathrm{h_{es}} \times [1 + (\mathrm{h_{es}}/\mathrm{D_{es}})]}$$

The relationship between VCFc and wall stress has been used as a load-independent index of myocardial contractility.[4,8,11] These data suggest that myocardial contractility does not change after the first 3 years of life. In contrast, premature infants, term neonates, and infants past the neonatal stage have higher mean VCFc and lower ESWS, with the observation most dramatic in the premature infant. This suggests a higher basal contractile state, which is not explained by afterload. Because the relationship between VCFc and ESWS is steeper in infants, they may be more sensitive to the effects of afterload.

REGIONAL WALL MOTION

The normal left ventricular end-systolic cross-sectional geometry is circular. With increased right ventricular pressure, the interventricular septum is flattened and the systolic left ventricle is D shaped. These changes are the result of altered septal motion, which regresses during the first week of life.

Diastolic Function

Ventricular compliance is the incremental change in ventricular volume for a change in pressure. The relationship between ventricular diastolic volume and pressure is nonlinear, and thus compliance decreases as preload increases. Compliance is affected by the intrinsic properties of the myofibrils, the connective tissue, and the pericardium. Comparison of right and left ventricular compliance in the fetus and the neonate reveals comparable right and left diastolic pressure-volume curves. In the adult, the left ventricular curve is shifted to the left, indicating that, at any given volume, left ventricular pressures are higher than right ventricular pressures. This observation is expected because hypertrophy is one of the determinants of diastolic function and because the fetal and neonatal right ventricular wall thickness is comparable to that of the left ventricle.

Analysis of the passive tension radius relationships in fetal, neonatal, and adult left ventricular myocardium suggests that the fetal ventricle is stiffer than the neonatal or adult ventricle. In the beating heart, diastolic compliance is affected by myocardial relaxation. Relaxation is an active process that requires transport of calcium from troponin C into the sarcoplasmic reticulum. Neonatal myocardium has a limited ability to sequester calcium, and this can impair relaxation.

The clinical assessment of diastolic function has relied on several echocardiographic and Doppler indexes. All have shortcomings, and unfortunately a clear understanding of diastolic function is even more elusive than that of systolic function. Echocardiographically determined rates of left ventricular posterior wall thinning increase dramatically during the first month of life, suggesting improved compliance or relaxation.[6] A similar index, the maximum velocity of lengthening of the left ventricular cavity, suggests that diastolic function is further impaired in premature infants.[3]

Doppler studies of atrioventricular valve and venous flow patterns have led to a number of parameters that are affected by diastolic ventricular function. In the fetus and the neonate, the proportion of blood that enters the ventricles during atrial systole (A wave) is higher than the flow during early diastole (E wave). This relationship can be expressed either as peak E and A velocities or areas or as the ratio of E to A velocities or areas. The isovolumic relaxation time can be measured from the end of aortic flow to the beginning of mitral valve flow. Retrograde flow into the hepatic veins during atrial systole occurs in normal infants and is usually attenuated by inspiration. If there is qualitatively more retrograde flow, or if the retrograde flow persists during inspiration, right ventricular compliance is probably reduced.

The interaction of ventricular relaxation, ventricular compliance, and preload make interpretation of these data difficult and prone to error. In clinical practice, infants who have persistent dominance of atrioventricular flow during atrial systole probably have some degree of diastolic dysfunction. Serial studies in individual infants might also be useful if there are no changes in preload.

Heart Rate

The embryonic heart rate gradually increases during cardiogenesis and then stabilizes in the second trimester. After birth, heart rate generally falls throughout childhood to adult levels. Heart rate is related to intrinsic properties of the pacemaker cells and endogenous catecholamines and hormones. These factors do not explain the remarkable relationship between heart rate and body size, ranging from more than 500 beats per minute in small rodents to less than 20 beats per minute in large mammals.

The major factor is likely the importance of ventricular-arterial coupling.[10] Blood flow occurs in a pulsatile fashion, and the total ventricular afterload is best described by vascular impedance, which includes the role of arterial diameter, distensibility, and length and wave reflections, as well as peripheral vascular resistance. Moreover, analysis of impedance permits the calculation of the energy required to move blood in a pulsatile fashion. Matching stroke volume and heart rate to arterial mechanics suggests that energy is minimized by high heart rates in a small aorta and low heart rates in a large aorta. In the embryo, developmental changes in aortic impedance resulting from changes in distensibility might favor lower heart rates despite the small size of the aorta.[13]

PART 6

Approach to the Neonate with Cardiovascular Disease

Kenneth G. Zahka

PRESENTATION OF CONGENITAL HEART DISEASE

Most patients with serious (life-threatening) congenital heart disease initially are seen by the physician in the neonatal period, many in the first several days of life. At this time, urgent intervention, either medical, surgical, or both, is often necessary. The mode of presentation depends on the cardiac lesion or combination of lesions, as well as on the timing of ductus arteriosus closure, fall in pulmonary vascular resistance, or ductus venosus closure. The superimposition of other disease processes in patients with serious structural cardiac disease can make the initial recognition and classification of such infants difficult and confusing. The most important examples of these superimposed disease processes are bacterial sepsis, pulmonary disease, and severe anemia. Such patients are at high risk; heart disease might not be recognized in a patient with clear bacterial sepsis, or perhaps worse, sepsis might go undiagnosed in a patient with obvious heart disease. The clinician must keep an open mind to all the diagnostic possibilities.

DIAGNOSTIC TECHNIQUES

Physical Examination

Cyanosis is one of the most important findings in recognizing congenital heart disease in an infant (Box 45-4).[17] Central cyanosis is the outward manifestation of reduced arterial oxygen saturation. The estimation of oxygen saturation based on the intensity of cyanosis can be inaccurate, however. The intensity of cyanosis is determined by the concentration of desaturated hemoglobin rather than by the actual oxygen saturation. Therefore, infants with marked polycythemia might appear

BOX 45–4 Distinctive Physical Signs

TO-AND-FRO SYSTOLIC AND DIASTOLIC MURMURS

Aortic stenosis and regurgitation
Truncal stenosis and regurgitation
Absent pulmonary valve syndromes: pulmonary stenosis and regurgitation
Left ventricular-to-aortic tunnel

DIFFERENTIAL CYANOSIS

Upper Normal and Lower Hypoxic

- Coarctation of the aorta, patent ductus arteriosus, ventricular septal defect
- Aortic arch interruption, patent ductus arteriosus, ventricular septal defect
- Mitral stenosis, patent ductus arteriosus
- Persistence of the transitional circulation with ductal right-to-left shunting and minimal atrial right-to-left shunting

Upper Hypoxic and Lower Normal

Transposition of the great arteries, coarctation of the aorta

cyanotic despite relatively minor arterial desaturation, because of the high absolute concentration of desaturated hemoglobin. On the other hand, infants with significant anemia appear relatively pink despite significant arterial desaturation. The latter situation is most common at 1 to 2 months of age, when normal physiologic anemia can occur. Infants who are somewhat cold, especially in the delivery room, can manifest impressive peripheral cyanosis, which does not reflect central arterial desaturation. Arterial desaturation can be a sign of right-to-left shunting of blood (as in a variety of congenital heart lesions and in persistent fetal circulation), transposition of the great arteries with delivery of systemic venous blood directly to the aorta, pulmonary venous desaturation caused by alveolar hypoxia (as in pulmonary edema, pneumonia, or atelectasis with perfusion of unventilated alveoli), or a combination of these factors.

The degree of respiratory distress should be noted because it is a clue to the cause of the problem. In general, cardiac lesions with reduction in pulmonary blood flow do not result in significant respiratory distress unless cyanosis is profound. Lesions with poor systemic output and acidosis, as well as those with increased pulmonary blood flow, cause respiratory distress. Infants with primarily pulmonary disease and those with superimposed pulmonary disease have respiratory distress (see Chapter 44).

Palpation of the cardiac impulse is helpful in assessing the anatomy and physiology of the lesion. Clear cardiac malpositions such as mirror-image dextrocardia might be obvious with palpation of the apex well to the right. A dramatically increased right or left ventricular impulse indicates increased ventricular pressure or, much more commonly, increased ventricular volume. An example would be an infant with total anomalous pulmonary venous return, in which both pulmonary and systemic venous returns enter the right side of the heart. Such an infant has a dramatically increased right ventricular impulse. In contrast, an infant with tetralogy of Fallot is likely to have no increase in cardiac impulse because pulmonary blood flow is reduced.

Auscultation of the heart sounds is valuable but rarely diagnostic. The second heart sound is of the greatest importance in evaluating congenital heart disease, but accurate assessment can be difficult and is a skill that takes a great deal of practice to acquire. The second heart sound is single in lesions associated with significant pulmonary hypertension, as well as in transposition, pulmonary atresia, and certain other conditions. Surprisingly, it is occasionally split in truncus arteriosus despite the presence of only one semilunar valve in this condition. The auscultation of cardiac murmurs in newborn infants rarely provides diagnostic or even specific information, with several exceptions. A to-and-fro systolic-diastolic murmur is characteristic of absent pulmonary valve syndrome, truncus arteriosus with truncal stenosis, and regurgitation. The loudest murmurs often occur in children with relatively benign lesions, such as small ventricular septal defects, whereas children with severe heart disease might have little or no murmur. Transient murmurs can be caused by tricuspid regurgitation or a patent ductus arteriosus.

Detection of hepatomegaly is helpful but also nonspecific. It indicates high systemic venous pressure, which can result from congestive heart failure of any cause or from conditions such as total anomalous pulmonary venous return or systemic arteriovenous fistula in which right ventricular volume is increased.

A careful assessment of the pulses and peripheral perfusion is critical in the infant with suspected heart disease. The femoral pulses are compared with an upper extremity pulse, usually the radial or brachial pulse, in assessing the possibility of aortic coarctation. Many experienced clinicians believe that such a careful comparison by palpation is more reliable than the determination of four-limb blood pressures (see discussion later). Conditions that cause a decreased pulse in all sites include any condition with decreased systemic blood flow and especially lesions that are dependent on the patency of the ductus arteriosus for systemic flow, such as hypoplastic left ventricle.

Blood Pressure Measurement

See also Chapter 31.

Blood pressure measurement is more helpful for following changes in hemodynamic condition than for diagnosing particular defects. This is true both for standard cuff pressures and for those obtained automatically by machine. The reason is that the act of inflating a cuff in a conscious infant is often associated with agitation and straining on the part of the infant. Nonsimultaneous measurements, therefore, are from somewhat different hemodynamic states, making comparisons of upper and lower extremity pressures unreliable. One approach to making such comparisons somewhat more reliable is to use two automatic machines simultaneously on the upper and lower extremities and then to switch the machines and repeat the procedure, taking the average difference between the two readings to correct for intermachine variation. There can be as much as a 15-mm Hg difference in the arm and leg blood pressure in normal newborns.[2]

Pulse Oximetry

See also Chapter 31 and Chapter 44, Part 3.

The pulse oximetry technique provides an excellent method of assessing arterial oxygen saturation noninvasively, using a probe attached to the palm or foot in the infant. Although the measurement of arterial blood gas tension is always useful, pulse oximetry avoids a painful needle stick, which can cause agitation, struggling, and underventilation, making such direct measurements somewhat unreliable.

Measurements should always be made from the right hand and from a foot to provide information about ductus arteriosus flow patterns. For example, patients with severe aortic coarctation or interruption and a patent ductus arteriosus providing flow from the pulmonary artery to the descending aorta have a much lower saturation in the feet than in the hands. On the other hand, patients with transposition and aortic coarctation can have a much higher saturation in the feet than in the hands because pulmonary arterial blood is highly saturated and passes from the pulmonary artery into the ductus arteriosus and descending aorta.

To prevent problems created by intermachine variability, one should use two machines simultaneously and then switch the leads, taking the average difference between the upper and lower extremity readings. Numerous studies have suggested that routine screening of all newborns can identify a greater percentage of infants with cyanotic congenital heart defects than clinical assessment alone, although screening in the first hours of life has a high false-positive rate.[4] Infants with left heart defects may be missed by this strategy, and careful clinical assessment remains important; in one study it was as effective as pulse oximetry for screening for critical heart defects.[15]

Hyperoxic Test

See also Chapter 44, Part 2.

For the hyperoxic test, the infant is allowed to breathe 100% oxygen, and an arterial blood gas measurement is obtained and compared with one obtained before the use of oxygen.[17] It can be performed either with arterial blood or with a transcutaneous monitor or pulse oximeter to estimate PO_2 or oxygen saturation. Patients with pulmonary disease alone generally have a rise in PO_2 of greater than 20 to 30 mm Hg or a rise in saturation of greater than 10%. Those with a fixed right-to-left shunt might have a small rise in oxygenation but generally less than these amounts. A fixed right-to-left shunt is a lesion in which no increase is possible either in pulmonary blood flow or in mixing of systemic and pulmonary venous return. Therefore, in such patients, pulmonary venous blood is already nearly completely oxygenated, and little additional oxygenation is possible. A good example is in tetralogy of Fallot, in which there is both a high resistance to pulmonary flow because of pulmonary stenosis and a right-to-left shunt through a ventricular septal defect.

Despite a common misconception, the hyperoxic test is not used to rule out congenital heart disease. Indeed, patients with large left-to-right shunts and systemic hypoxemia might have large increases in oxygenation because added inspired oxygen normalizes pulmonary venous saturation, which may be low as a result of pulmonary edema and the accompanying oxygen diffusion gradient. Patients with mixing of pulmonary and systemic venous return and no obstruction to pulmonary flow could also have a large rise in O_2 saturation because additional inspired oxygen can cause pulmonary arteriolar vasodilation, raising pulmonary flow and increasing the quantity of pulmonary venous blood available for admixture. The best example of this phenomenon is total anomalous pulmonary venous return without obstruction, in which there is a large amount of pulmonary flow, but cyanosis is caused by mixing that occurs in the right atrium.

Supplemental inspired oxygen can increase arterial saturation somewhat because of additional increases in pulmonary flow. The same effect can be seen with the use of pulmonary vasodilators such as prostaglandin E_1. If supplemental oxygen is continued, however, this increase in an already high pulmonary flow could be detrimental, leading to pulmonary edema, congestive heart failure, and eventually acidosis.

Radiography

See also Chapter 37.

The chest radiograph can provide subtle information concerning possible types of heart disease, but the most common use is for assessing heart size and determining pulmonary blood flow (Box 45-5 and Figs. 45-10 and 45-11). For the determination of heart size, the width of the cardiothymic silhouette is measured and compared with the width of the chest at its largest dimension. The ratio should be 0.65 or less. Because true posteroanterior projections are unusual in infants, the measurement is made with an anteroposterior chest film; the most reliable measurements are from a film on which a good inspiration was obtained, with the diaphragm seen at the posterior margin of the 9th or 10th rib. The heart can appear falsely enlarged if the film is taken on expiration. One could be seeing heart, thymus, and pericardial fluid as part of the cardiothymic silhouette. The degree of pulmonary vascularity should be noted as normal, increased, or decreased, and the presence or absence of interstitial fluid, which is seen in pulmonary edema, must also be noted. Perhaps with the exception of the position of the aortic arch, which is ascertained by the deviation of the trachea or massive cardiomegaly, the chest

BOX 45–5 Distinctive Radiographic Signs

Transposition of the great arteries with ventricular septal defect and pulmonary stenosis

MASSIVE CARDIOMEGALY (see Fig. 45-11)
Ebstein anomaly

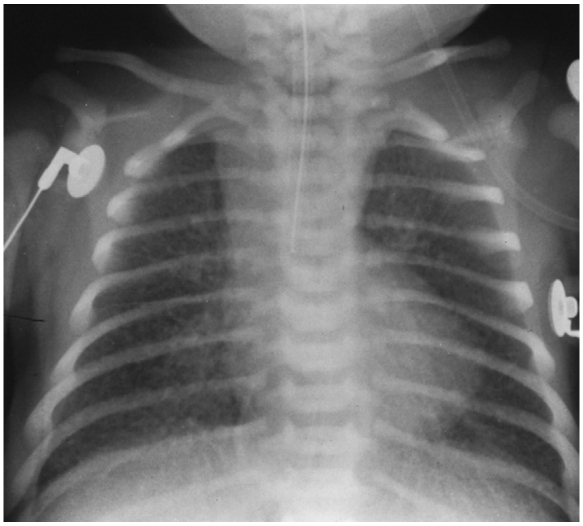

Figure 45–10. Chest radiograph of a newborn with an obstructed total anomalous pulmonary venous connection to innominate vein through the vertical vein. Bilateral pulmonary edema is due to pulmonary venous congestion.

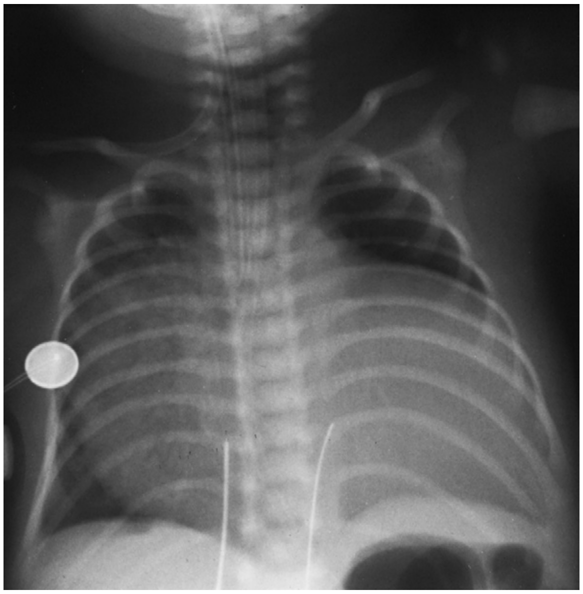

Figure 45–11. Massive cardiomegaly is present in this chest radiograph of a 1-day-old infant with severe Ebstein malformation of the tricuspid valve. The entire right cardiac silhouette is from right atrial enlargement. Diminished pulmonary vascularity is due to associated pulmonary atresia.

radiograph is relatively insensitive for specific cardiac diagnoses. It should not be used to exclude important heart defects when there is clinical suspicion of heart disease.[5]

Electrocardiography

Use of the electrocardiogram in the diagnosis of congenital heart disease is largely applicable to ventricular hypertrophy. Normal newborn infants have a relative predominance of the right ventricle over the left ventricle. This predominance shifts to left ventricular predominance in the first year of life because of the fall in pulmonary artery pressure and the consequent fall in right ventricular systolic pressure. All electrocardiographic interpretations in children must be made relative to the normal right or left ventricular predominance existing at that particular age.

Electrocardiographic diagnosis of hypertrophy can be determined by recognizing that the right ventricle is oriented to the right, superior, and anterior, whereas the left ventricle is oriented to the left, inferior, and posterior. Leads that represent these orthogonal directions are V_5 and V_6 (right-left), aVF (superior-inferior), and V_1 and V_2 (anterior-posterior). One can then compare the forces present in these leads with normal standards for age to arrive at a judgment of relative ventricular predominance.

The T-wave main vector is an additional aid for diagnosing right ventricular hypertrophy. In normal neonates, the T wave is upright in leads V_1, $_RV_3$, and $_RV_4$ and inverts by 1 week of age, remaining inverted until about age 5 to 8 years. If it is upright between the ages of several days and 5 years, right ventricular hypertrophy is likely.

Except for the diagnosis of arrhythmias, the electrocardiogram is rarely diagnostic in the evaluation of the newborn with cardiac disease (Box 45-6). However, although one might suppose that a lesion obstructing the left ventricle, such as aortic coarctation, would produce left ventricular hypertrophy, in fact such lesions are seen more often with right ventricular hypertrophy, probably because, in the intrauterine circulation, the right ventricle is responsible for more of the combined ventricular output when the left ventricle is obstructed. The same is often true of lesions obstructing the right ventricle, which are often seen with left ventricular hypertrophy.

The electrocardiographic picture varies greatly within each of the diagnostic groups, and the electrocardiogram of infants with serious disease such as transposition is often completely normal. In practice, the clinician uses the electrocardiogram to confirm the impression that there is heart disease when the electrocardiogram fits the suspected diagnosis.

Echocardiography

Cardiac ultrasonography is the definitive diagnostic method for evaluating suspected cardiac disease in infants. It is noninvasive and safe, can be done at the bedside of sick neonates, and can be used successfully in premature infants of all sizes. The resolution is sufficient to make complete anatomic diagnoses in even the smallest hearts. Doppler echocardiography and color flow Doppler mapping have added the ability to study intracardiac and extracardiac flow patterns for assessing valve function and sites of obstruction.

BOX 45–6 **Distinctive Electrocardiographic Signs**

Left axis deviation
Endocardial cushion defect
Tricuspid atresia
Noonan syndrome
Left ventricular hypertrophy

The quality of the diagnostic information is such that many infants who would previously have undergone cardiac catheterization are now referred for cardiac surgery on the basis of the echocardiogram alone. Patients should be recommended for echocardiography on the basis of a cardiac evaluation, including physical examination, oxygen saturation measurement, electrocardiography, and other modalities. Echocardiography must be directed with knowledge of the infant's presenting signs and the results of the evaluation to date. Otherwise, important and often subtle findings might be missed.

CARDIAC IMAGING

Echocardiography relies on the reflection of ultrasound from interfaces in cardiac tissue such as those between arterial walls and the blood. Because the velocity of ultrasound in tissue is known, the time between the generation of the ultrasound and its reflection back to the transducer is proportional to distance. The strength of the reflections is a function of the tissue qualities. When arrays of different ultrasound crystals are coordinated simultaneously, two-dimensional images can be assembled. These are obtained from many standard precordial, subcostal, and suprasternal views. Evaluation of multiple planes from these sites results in a complete picture of cardiac structure (Box 45-7). Three-dimensional echocardiography can provide improved understanding of valve or spacial anatomy in selected neonates.

Technically, excellent transthoracic studies are the rule in neonates except in the postoperative period and obviously in the operating room after cardiopulmonary bypass. These limitations have been addressed by the development of pediatric transesophageal transducers, and intraoperative transesophageal echocardiography to assess the results of surgery has become routine.[3] Because of the relative size of the transducer and the proximity to the airway, postoperative neonates who need transesophageal echocardiography are intubated and sedated.

A quantitative approach to echocardiography is essential even in the neonate. Measurement of ventricular diastolic and systolic dimensions can be made either from two-dimensional images or from M-mode recordings. In M-mode recordings, a cursor is directed through the two-dimensional image across the structure to be measured (e.g., the left ventricle), and a continuous recording of dimensions along that cursor is made with time. Quantitative measurement of ventricular volume is done by planimetry of two-dimensional images. This quantitative approach often suggests physiologic abnormalities, such as left ventricular hypertrophy caused by increased left ventricular pressure.

BOX 45–7 Echocardiographic Definition of Cardiac Structure

- Abdominal and atrial situs
- Systemic and pulmonary venous connections
- Mitral and tricuspid valve anatomy
- Atrioventricular connections
- Ventricular morphologic features, size, and wall thickness
- Ventriculoarterial connections
- Semilunar valve anatomy
- Aortic arch anatomy
- Pulmonary artery anatomy
- Thymus

DOPPLER ECHOCARDIOGRAPHY

Doppler echocardiography measures blood flow velocity and direction. Pulsed Doppler selects a specific site in the heart (e.g., the aortic valve) and measures velocity and direction with time. The maximum velocity that pulsed Doppler can detect is limited and is affected by the distance from the transducer and the frequency of the ultrasound transducer. The advantage of pulsed Doppler is that the velocities being measured are range-gated; that is, the velocities measured are from a specific structure within the heart.

Continuous-wave Doppler overcomes the problem of aliasing but sacrifices the range-gating. Velocities measured by continuous-wave Doppler could come from any structure along the cursor through the two-dimensional image. Continuous-wave Doppler is useful for measuring high-velocity flow such as occurs with stenotic or regurgitant valves.

Pulsed Doppler and continuous-wave Doppler provide highly quantitative velocity data from limited areas of the heart displayed as a function of time. Color flow mapping provides velocity information at many simultaneous sites encoded by color directly on the two-dimensional image. Blood flow toward the transducer is coded in shades of yellow or red, and flow away from the transducer is coded in shades of blue. The higher the velocity, the brighter the color that codes the flow. These color maps are updated up to 30 times per second and give a remarkable picture of the direction of blood flow through the heart. Color flow mapping dramatically enhances the identification of intracardiac shunts and disturbed blood flow at valves and along blood vessels.

The application of the Bernoulli principle to cardiac Doppler imaging has facilitated the quantitative assessment of physiologic changes caused by congenital heart defects. The Bernoulli principle in its simple form states that the change in pressure (ΔP) across an obstruction of flow is proportional to a constant times the square of velocity distal to the obstruction.[7,9,11]

MEASUREMENT OF CARDIAC FUNCTION

Table 45-4 and Box 45-8 summarize the data available from two-dimensional imaging and Doppler studies to define cardiac systolic and diastolic function.[14] The use of two-dimensional echocardiographic and Doppler parameters to define pulmonary artery pressure is outlined in Table 45-5.[8,12,16]

Computed Tomography and Magnetic Resonance Imaging

Myocardial tissue Doppler indexes[10]

of images has made these modalities available to the neonate. Magnetic resonance and computed tomography imaging in the neonate are particularly strong in delineating the anatomy of the aortic arch, pulmonary artery, pulmonary veins, and ventricular volumes.[6,13]

Computed tomography clearly demonstrates the relationship of the bronchi and the cardiac structures, which is invaluable in assessing respiratory distress in neonates with vascular rings and tracheal compromise resulting from enlarged pulmonary arteries. Software enhancements and cardiac gating have also helped define ventricular anatomy and function. Flow studies are possible and permit calculations similar to those of Doppler echocardiography for pressure gradients.

The principal disadvantage of these modalities for the sick neonate is the inability to come to the bedside for the study. However, ventilators and monitors are available that make these studies possible.

TABLE 45–5 Two-Dimensional and Doppler Assessment of Pulmonary Hypertension: Interpretation of Normal Values

Variables	Values
Two-Dimensional Assessment	
RV hypertrophy	Normal < 3 mm
Mid-systolic pulmonary valve closure	Normal: none
Systolic septal flattening: circularity index	Normal > 93%
Systolic time interval: RV pre-ejection period and RV ejection time	Normal < 0.3 indicates normal PA diastolic pressure
Doppler Assessment	
Systolic time interval: RV pre-ejection period and RV ejection time	Normal < 0.3 indicates normal PA diastolic pressure
RVOT acceleration time/ejection time	Normal > 0.36 indicates normal mean PA pressure
Tricuspid regurgitation velocity	Low velocity indicates low RV systolic pressure
Pulmonary regurgitation velocity	Low velocity indicates low PA diastolic pressure
Ductal velocity	High velocity indicates low PA diastolic pressure
Ventricular septal defect velocity	High velocity indicates low RV systolic pressure

PA, pulmonary artery; RV, right ventricular; RVOT, right ventricular outflow tract.

Cardiac Catheterization

Although routine neonatal diagnostic cardiac catheterization is rare, there remains a role for diagnostic catheterization and angiography, especially when decisions must be made regarding neonatal repair or palliation of complex defects. Pressure data can usually be inferred from echocardiography but directly measured only by catheterization. Neonatal repair of many defects can be undertaken without precise hemodynamic measurement of pressure and blood flow and calculation of vascular resistance. Elective catheterization is usually more useful after neonatal palliation with shunts or pulmonary artery bands to assess pulmonary artery hemodynamics. An understanding of the principles of hemodynamic catheterization is, however, essential for postoperative care, when atrial and arterial monitoring catheters are available for oxygen sampling and pressure measurement.

DIAGNOSTIC GROUPS OF CONGENITAL HEART DISEASE

The spectrum of congenital heart disease includes scores of particular lesions with variable presentations within each diagnosis. These variations often determine the type and timing of corrective cardiac surgery, but they do not preclude a general grouping of defects. Grouping of defects by symptoms enhances the recognition of which infants require echocardiography, transfer to a specialized center, and, most important, prostaglandin E_1 to maintain or restore ductal patency.

The reduction in neonatal cardiovascular morbidity and mortality rates since the introduction of prostaglandin E_1 in the late 1970s cannot be underestimated, and the timely identification of infants with ductal-dependent heart defects is essential. These defects include those with restricted pulmonary blood flow (e.g., pulmonary atresia), restricted systemic blood flow (critical aortic stenosis or coarctation), and separate circulations with poor mixing (transposition of the great arteries). Preliminary diagnosis identifies which infants have excessive pulmonary flow and limited systemic blood flow, for whom supplemental oxygen will be detrimental, such as infants with hypoplastic left heart syndrome.

A summary of defects by diagnostic category is given in Box 45-9. Varieties of several defects appear in more than one category if there is a spectrum of common clinical presentations.

Cyanosis

Varying degrees of cyanosis might be present in many neonates with congenital heart disease at presentation. Cyanosis is the most prominent feature, as opposed to respiratory distress, congestive heart failure, or poor systemic flow, in infants with restricted pulmonary blood flow and those with separate circulations and poor mixing. A lesser degree of hypoxia is seen with mixing lesions, pulmonary disease, or pulmonary edema.

BOX 45–9 Classification of Congenital Heart Disease

SEVERE CYANOSIS CAUSED BY SEPARATE CIRCULATIONS AND POOR MIXING

D-Transposition of the great arteries
D-Transposition of the great arteries and ventricular septal defect
Double-outlet right ventricle with subpulmonary ventricular septal defect (Taussig-Bing)

SEVERE CYANOSIS CAUSED BY RESTRICTED PULMONARY BLOOD FLOW

Tetralogy of Fallot
Double-outlet right ventricle with subaortic ventricular septal defect and pulmonary stenosis
Tricuspid atresia
Pulmonary atresia with intact interventricular septum
Critical pulmonary stenosis
Ebstein anomaly
Single ventricle with pulmonary stenosis
Persistent pulmonary hypertension

MILD CYANOSIS CAUSED BY COMPLETE MIXING WITH NORMAL OR INCREASED PULMONARY BLOOD FLOW

Total anomalous pulmonary venous connection
Truncus arteriosus
Single ventricle without pulmonary stenosis
Double-outlet right ventricle with subaortic ventricular septal defect

SYSTEMIC HYPOPERFUSION AND CONGESTIVE HEART FAILURE WITH MILD OR NO CYANOSIS

Aortic stenosis*
Coarctation of the aorta and aortic arch interruption
Hypoplastic left heart syndrome
Multiple left heart defects
Single ventricle with subaortic stenosis or coarctation of the aorta
Myocardial diseases: cardiomyopathy and myocarditis*
Cardiac tumor*
Arteriovenous malformation*
Hypertension*

ACYANOSIS WITH NO OR MILD RESPIRATORY DISTRESS

Normal murmurs
Pulmonary stenosis
Ventricular septal defect†
Atrial septal defect
Endocardial cushion defect†
Patent ductus arteriosus†
Aortopulmonary window†
L-Transposition of the great arteries
Arteriovenous malformation
Hypertension

---

*No symptoms with mild forms of disease.

†Congestive heart failure can develop as left-to-right shunt increases with decrease in pulmonary vascular resistance.

SEVERE CYANOSIS CAUSED BY SEPARATE CIRCULATIONS AND POOR MIXING

Severe cyanosis caused by separate circulations and poor mixing is a diagnostic group that includes lesions in which there is prominent cyanosis but a normal or increased pulmonary blood flow. The neonates have transposition of the great arteries with a small atrial or ventricular septal communication or a related lesion with similar blood flow patterns (double-outlet right ventricle with subpulmonary ventricular septal defect). In such cases, the cyanosis is due to inadequate mixing between the systemic and pulmonary venous returns, so that the systemic venous return is delivered to the aorta through the right ventricle, with little admixture of oxygenated blood. Patients with this group of defects could benefit from a patent ductus arteriosus because the ductal flow enhances atrial mixing.

SEVERE CYANOSIS CAUSED BY RESTRICTED PULMONARY BLOOD FLOW

In the lesions of severe cyanosis caused by restricted pulmonary blood flow, there is an anatomic obstruction to pulmonary blood flow, including obstruction of the pulmonic valve or tricuspid valve. Because neonates with these lesions are dependent on patency of the ductus arteriosus, a prostaglandin E_1 infusion should be started immediately. A dramatic improvement in saturation resulting from prostaglandin E_1 infusion confirms that a particular lesion is in this group.

Within this group with decreased pulmonary flow, several lesions have characteristic findings that allow one to be more confident of the actual diagnosis. For example, a cyanotic infant with decreased pulmonary flow and a huge cardiac silhouette most likely has Ebstein anomaly of the tricuspid valve. A small heart and a harsh ejection murmur but decreased pulmonary flow most likely indicate tetralogy of Fallot. The murmur is due to a stenotic, but not atretic, pulmonic valve.

MILD CYANOSIS CAUSED BY COMPLETE MIXING WITH NORMAL OR INCREASED PULMONARY BLOOD FLOW

Most patients with lesions in the diagnostic group of mild cyanosis caused by complete mixing with normal or increased pulmonary blood flow have evidence of pulmonary overcirculation, as seen on the chest radiograph, and their most prominent presenting sign is usually respiratory distress. In the mixing lesions, arterial desaturation is due to mixing of systemic and pulmonary venous blood before ejection into the aorta. Because pulmonary flow is increased or normal, cyanosis is not profound.

Because pulmonary flow is capable of increasing under the influence of inhaled oxygen, the arterial saturation often rises dramatically with the hyperoxic test. Arterial saturation does not become normal, however, because some admixture of systemic and pulmonary venous blood is always present. This decreased response to oxygen helps differentiate these infants from those with primarily left-to-right shunts and mild cyanosis caused by pulmonary overcirculation and resultant pulmonary edema. Similarly, infants with pulmonary edema caused by left ventricular dysfunction and high pulmonary venous pressures have a normal response to oxygen.

Examples of a mixing lesion with increased pulmonary flow are total anomalous pulmonary venous connection, truncus arteriosus, and single ventricle without pulmonary stenosis. Infants with these defects do not require prostaglandin E_1 unless there are associated defects. A patent ductus arteriosus is unlikely to be deleterious if prostaglandin E_1 is started empirically. In contrast, supplemental oxygen or hyperventilation can dramatically increase pulmonary blood flow and decrease systemic blood flow and should be avoided in this group of babies.

Systemic Hypoperfusion and Congestive Heart Failure with Mild or No Cyanosis

Some degree of hypoperfusion might be present in infants with cyanosis, especially with the injudicious use of oxygen. However, infants with systemic hypoperfusion and congestive heart failure with mild or no cyanosis have poor systemic perfusion as the most prominent feature.[1] The classic example of this group of lesions is hypoplastic left heart syndrome. The babies with these lesions are ductal dependent for systemic flow because all or a large portion of systemic flow must traverse the ductus arteriosus from the pulmonary artery. Also in this group of lesions are critical aortic stenosis, critical coarctation of the aorta, and aortic arch interruption. In these lesions, the mild cyanosis might be limited to the lower portion of the body because the ductus arteriosus perfuses the descending aorta with a variable degree of retrograde ascending aortic flow.

The differential diagnosis for this group includes a number of cardiac conditions that are not dependent on the ductus arteriosus for systemic flow, as well as several noncardiac conditions. Cardiac conditions that do not depend on a patent ductus arteriosus and that include systemic hypoperfusion at presentation include cardiomyopathies and arrhythmias. Noncardiac conditions that could have systemic hypoperfusion at presentation, mimicking forms of congenital heart disease, include neonatal sepsis and metabolic disease.

Acyanosis with No or Mild Respiratory Distress

In the neonatal period, most infants with uncomplicated left-to-right shunts, including ventricular septal defect and patent ductus arteriosus, are in the group of acyanosis with no or mild respiratory distress. Prostaglandin E_1 is not necessary; however, unlike the infants with a single ventricle, these infants, when given supplemental oxygen, rarely have difficulty with impaired systemic flow because of excessive pulmonary flow. Respiratory distress or poor perfusion should suggest an associated obstruction of the left side of the heart.

CYANOTIC HEART DEFECTS: POOR MIXING

D-Transposition of the Great Arteries

ANATOMY AND PATHOPHYSIOLOGY

In D-transposition of the great arteries, the aorta connects to the right ventricle, and the pulmonary artery connects to the left ventricle. The aorta is anterior and slightly to the right, and the pulmonary artery is posterior and to the left.

In contrast to the blood flow pattern in the normal heart, in which the pulmonary and systemic circulations are in series, in transposition of the great arteries, the pulmonary and systemic circulations are in parallel. Thus, the venous blood returning to the right atrium flows through the tricuspid valve into the right ventricle and is ejected into the aorta, supplying the body with poorly oxygenated blood, which then returns to the right atrium to repeat the cycle. Fully oxygenated blood from the lungs enters the left atrium, flows through the mitral valve into the left ventricle, and is ejected into the pulmonary artery to perfuse the lungs and return to the left atrium without delivering oxygen to the body. In the absence of shunting across connections between the systemic and pulmonary circulations, this results in profound, lethal systemic hypoxia.

The persistence of two fetal connections, the foramen ovale and the ductus arteriosus, provides sites for intracardiac shunting during the first hours and days of life. After spontaneous closure of the ductus arteriosus, bidirectional shunting at the atrial level is essential for survival.

Right ventricular pressure is high because of high vascular resistance in the aorta and systemic vasculature. The high right ventricular pressure and systemic resistance maintain the right ventricular muscle mass. With the fall in pulmonary vascular resistance, left ventricular and pulmonary artery pressures fall, which results in regression of the normal neonatal left ventricular hypertrophy.

ASSOCIATED DEFECTS

Associated defects have a dramatic effect on the presentation and pathophysiology of newborn infants with transposition of the great arteries. At a minimum, an atrial septal defect with balanced bidirectional shunting is essential for survival.[92] This shunting occurs in a phasic manner over the cardiac cycle, with shunting from the left to right atrium favored during ventricular systole. The addition of a patent ductus arteriosus permits nearly exclusive shunting from the aorta to the pulmonary artery at the arterial level, with an equal volume of left-to-right atrial shunting at the atrial level. This combination provides excellent palliation of the systemic hypoxia.

A ventricular septal defect occurs in about 25% of infants with transposition of the great arteries. Because of the relative aortic and pulmonary artery resistance, flow at a ventricular septal defect is from the right ventricle to the left ventricle and pulmonary artery in systole. This right-to-left shunt is usually balanced by a left-to-right shunt at the atrial level or the ventricular level in diastole.

Arch obstruction, either coarctation of the aorta or aortic arch interruption, occurs in association with transposition of the great arteries and ventricular septal defect.[82] Flow to the descending aorta comes from the pulmonary artery and has a high saturation. Valvular and subvalvular pulmonary stenosis limits pulmonary blood flow and shunting from the left to the right atrium and from the right ventricle to the pulmonary artery.

CLINICAL PRESENTATION

Transposition of the great arteries is the most common cyanotic heart defect identified in the first week of life, and the diagnosis should be considered in any cyanotic neonate. Fetal diagnosis is common but not uniform; however, even with prenatal diagnosis, profound hypoxia due to a highly restrictive patent foramen ovale can lead to rapid deterioration and death in the first hours of life.[50,98] Respiratory symptoms are absent or limited to hyperpnea or tachypnea without dyspnea. The second heart sound is persistently single in transposition of the great arteries because of the anterior position of the aorta and the posterior position of the pulmonary artery. A holosystolic murmur suggests an associated ventricular septal defect; a systolic ejection murmur is heard with pulmonary stenosis. In the absence of these associated defects, murmurs are typically not heard. The peripheral pulses are normal unless coarctation of the aorta is present. Persistent ductal patency or high pulmonary vascular resistance will affect the clinical findings of an associated ventricular septal defect or coarctation of the aorta.

LABORATORY EVALUATION

The electrocardiogram is normal, although right ventricular hypertrophy might be evident after the first week of life. Similarly, the classic egg-shaped heart with increased pulmonary vascularity on the chest radiograph might not be seen in the newborn period. Echocardiography defines the associated defects and coronary artery anatomy.[79] Preoperative identification of anatomic coronary variations, including an intramural course of the coronary arteries, is central to surgical planning for the arterial switch operation.[61] Cardiac catheterization is usually reserved for neonates requiring balloon atrial septostomy, but it is occasionally useful for clarifying coronary or other anatomic details (Fig. 45-12).

MANAGEMENT AND PROGNOSIS

Establishing patency of the ductus arteriosus with prostaglandin E_1 in newborn infants who have transposition of the great arteries often improves arterial oxygenation by increasing shunting from the aorta into the pulmonary artery. This in turn increases the pulmonary venous return, distending the left atrium and facilitating shunting from the left to the right atrium of fully saturated blood across the foramen ovale.

If prostaglandin E_1 treatment does not result in adequate systemic oxygenation, a balloon atrial septostomy is performed. At cardiac catheterization or at the bedside with echocardiographic guidance, a balloon-tipped catheter is advanced from the inferior vena cava into the right atrium and through the foramen ovale to the left atrium. The balloon is inflated with dilute radiographic contrast medium. The catheter is then sharply tugged, resulting in rapid withdrawal of the inflated balloon from the left atrium to the junction of the right atrium and inferior vena cava. The atrial septum tears, enlarging the foramen ovale into an atrial septal defect and allowing improved mixing of the systemic and pulmonary venous return at the atrial level.

History

Surgical management of transposition of the great arteries has changed dramatically since the 1960s and, in particular, since the 1980s. Surgical creation of an atrial septal defect with the technique described by Blalock and Hanlon in 1950 was eventually replaced by the atrial baffling operations described by Senning in 1959 and Mustard in 1964. In these operations, the arterial and ventricular connections remained transposed, and the venous inflow into the atria was redirected. The superior and inferior vena caval blood was tunneled across the atrium to the mitral valve, and the pulmonary veins were directed to the tricuspid valve.

This physiologic repair resulted in fully oxygenated blood in the right ventricle and aorta and in poorly oxygenated blood in the left ventricle and pulmonary artery; however, the anatomic ventriculoarterial relationships of the heart remained

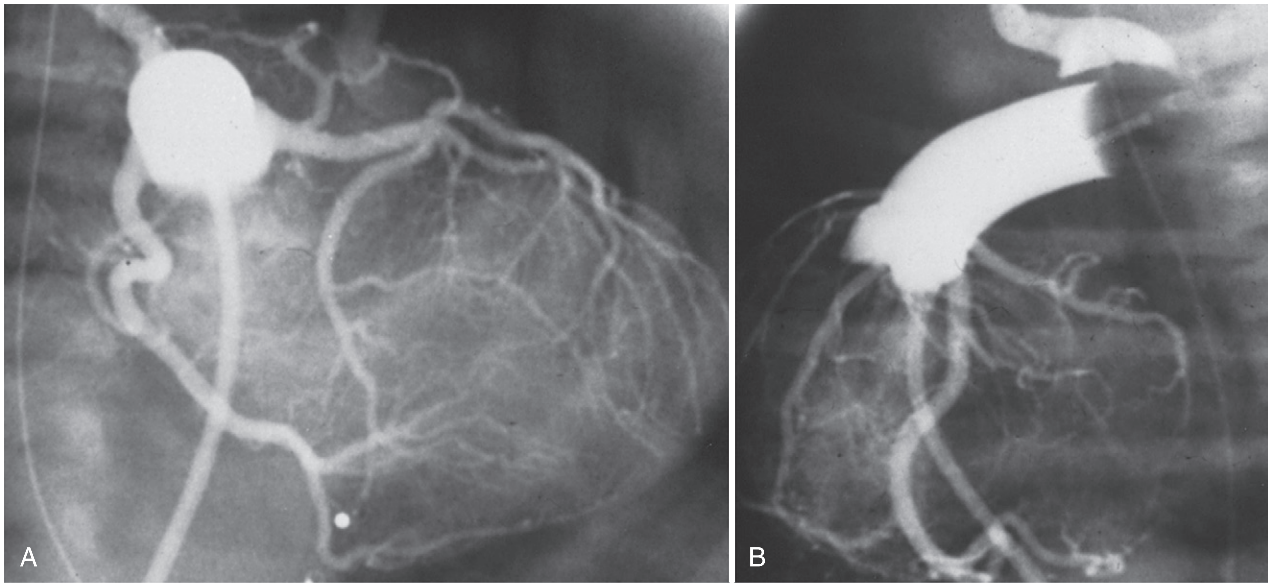

Figure 45–12. **A**, Anterior “laid back” view in balloon occlusion aortogram demonstrating the most common coronary arterial anatomy found in transposition of great arteries. Great arteries are front to back, and the right coronary artery arises from the right posterior-facing sinus, whereas the left coronary artery arises from the left posterior-facing sinus and gives rise to the left anterior descending and circumflex arteries. **B**, Lateral view of the same, showing ideal balloon position and occlusion of the aorta at the time of injection.

abnormal. Long-term postoperative problems included atrial arrhythmias, pulmonary and systemic venous obstruction, and right ventricular enlargement and dysfunction.[3,42]

Arterial Switch Operation

Jatene and later Yacoub pioneered the anatomic repair of transposition of the great arteries, using the arterial switch operation. This operation requires transection of the aorta and pulmonary artery to move the pulmonary artery anteriorly to the right ventricle and the aorta posteriorly to the left ventricle. The coronary arteries are moved from their original position on the aorta to the newly created aorta, and atrial and ventricular septal defects are repaired.

The arterial switch operation in infants with transposition of the great arteries and with an intact ventricular septum is optimally performed in the first 2 weeks of life. During this time, the left ventricle has sufficient hypertrophy to support systemic blood pressure. After 2 weeks, unless there is a large ventricular septal defect, left ventricular pressure is low, and the left ventricular muscle mass has regressed in a similar fashion to that of the right ventricle in children with normally related great arteries.

The follow-up to date for the arterial switch operation is favorable.[63,98,107] Risk factors for early mortality include prematurity and right ventricular hypoplasia.[16] Coronary anatomy (especially intramural coronary arteries), a risk factor in the earlier experience, can now be managed effectively, although with a higher hospital morbidity.[16,61] Long-term follow-up studies demonstrate excellent ventricular function, normal rhythm, and a low incidence of obstruction at the aortic and coronary suture lines.[23,88] Narrowing in the supravalvular pulmonary area could require subsequent surgery or catheter interventions.[5,31,74,98] Dilation of the neoaortic root and aortic regurgitation are found in some children but rarely require intervention.[62,98] Neurodevelopmental outcome is, in general, good in infants who do not require intraoperative circulatory arrest. Motor deficits, rather than impaired intelligence quotient scores, are seen in infants with transposition of the great arteries who had circulatory arrest.[15]

CYANOTIC DEFECTS: RESTRICTED PULMONARY BLOOD FLOW

Tetralogy of Fallot

ANATOMY AND PATHOPHYSIOLOGY

In 1888, Fallot described the association of infundibular (subvalvular) and valvular pulmonary stenosis, a large ventricular septal defect, a large aorta overriding the ventricular septum, and right ventricular hypertrophy.

A variable degree of pulmonary artery hypoplasia, an atrial septal defect or foramen ovale, patent ductus arteriosus, or systemic-to-pulmonary collateral vessels are often present. In the most severe form of tetralogy of Fallot, atresia of the pulmonary valve or of the entire right ventricular outflow tract (OFT) and main pulmonary artery occurs.

Obstruction of the right ventricular OFT reduces pulmonary blood flow and produces systemic arterial desaturation by diverting poorly oxygenated right ventricular blood across the ventricular septal defect into the ascending aorta. The extent of right-to-left shunting is determined by the relative resistance to systemic and pulmonary blood flow. Whereas systemic resistance is determined by peripheral arteriolar resistance, total resistance to pulmonary blood flow is the combination of pulmonary infundibular, valvular, and arteriolar resistance. Acutely increasing the pulmonary infundibular obstruction, such as probably occurs with the release of endogenous catecholamine, exacerbates the shunting.

ASSOCIATED DEFECTS

Right aortic arch is seen in about 25% of neonates with tetralogy of Fallot. Surgically important variants include origin of the anterior descending coronary artery from the right coronary artery. This branch crosses the right ventricular OFT at the level of the site of the infundibular incision and could limit the possibility of excising the subpulmonary obstruction. The branch pulmonary arteries might be discontinuous and supplied by one or more collateral vessels from the aorta. Tetralogy of Fallot with absent pulmonary valve includes hypoplasia of the pulmonary valve annulus and rudimentary cusps. Infants with this defect also have marked poststenotic dilation of the branch pulmonary arteries and compression of the bronchi.

CLINICAL PRESENTATION

The spectrum of the clinical presentation of tetralogy of Fallot is directly related to the severity of the pulmonary stenosis. The intensely cyanotic newborn infant generally has severe pulmonary stenosis or atresia and markedly diminished pulmonary blood flow. The minimally cyanotic or even acyanotic newborn infant being examined for a systolic murmur has just enough pulmonary stenosis to prevent a left-to-right shunt through the ventricular septal defect without producing a right-to-left shunt.

There is usually a palpable right ventricular impulse, reflecting the right ventricular hypertension, and a single second heart sound with an absent pulmonary component because of the anterior location of the aorta and the marked abnormality of the pulmonary artery OFT. The systolic ejection murmur heard in neonates with tetralogy of Fallot is produced by turbulent blood flow across the pulmonary stenosis; therefore, the intensity of the murmur is directly related to the amount of pulmonary blood flow and inversely related to the severity of the pulmonary obstruction.

The absence of a systolic ejection murmur in children with tetralogy of Fallot implies atresia of the right ventricular OFT. In this case, a continuous murmur indicates blood flow through a patent ductus arteriosus or through systemic-to-pulmonary collateral vessels as the sole source of pulmonary blood flow.

LABORATORY EVALUATION

The electrocardiogram of the neonate is normal. Electrocardiographic criteria for right ventricular hypertrophy develop during the first month of life. The echocardiogram demonstrates the ventricular septal defect and aortic override (Fig. 45-13). Of particular echocardiographic importance is documentation of the sites of pulmonary obstruction, with determination of the size of the main and branch pulmonary arteries and the presence of a patent ductus arteriosus or collateral vessels.

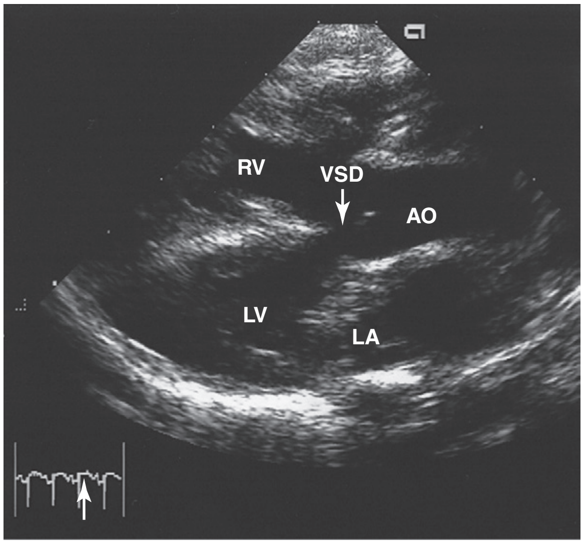

Figure 45–13. Echocardiogram showing parasternal long-axis view in a newborn infant with tetralogy of Fallot. The right ventricle (RV) is anterior, and left ventricle (LV) is posterior, with a large ventricular septal defect (VSD) and overriding aorta (AO). LA, left atrium.

Coronary artery anatomy can usually be defined. In newborn infants, the chest radiograph does not show the typical “boot-shaped” heart, although decreased vascularity or a right aortic arch might be evident. Cardiac catheterization is now only indicated before surgery if the pulmonary artery anatomy and sources of pulmonary blood flow cannot be defined noninvasively by echocardiogram, computed tomography, or magnetic resonance imaging.

MANAGEMENT AND PROGNOSIS

Neonates with severe cyanosis are stabilized by an infusion of prostaglandin E_1 to dilate the ductus arteriosus and increase pulmonary blood flow. These infants often have severely hypoplastic pulmonary arteries and must have a palliative procedure to establish a source of pulmonary blood flow. This includes a systemic-to-pulmonary shunt, with either a direct connection of the subclavian artery to the pulmonary artery (Blalock-Taussig shunt) or a synthetic tubular graft (Gore-Tex) between the aorta or one of its branches and the pulmonary artery. Balloon dilation or stenting of the stenotic pulmonary valve has been favored in a few centers as an alternative to shunts.[27] In babies with marked pulmonary artery hypoplasia, the right ventricular OFT can be widened surgically without closing the ventricular septal defect. Rehabilitation of branch pulmonary artery stenosis by surgery or interventional catheterization is important either at the time of primary repair or as part of a staged approach.[57]

Neonatal repair of tetralogy of Fallot is feasible for babies with appropriate pulmonary artery anatomy. Surgical repair of tetralogy of Fallot consists of closure of the ventricular septal defect, excision of the pulmonary stenosis, and enlargement of the right ventricular OFT with a patch. In the absence of marked pulmonary artery hypoplasia or unfavorable coronary artery anatomy, surgery can be undertaken at virtually any age.[86]

Tricuspid Atresia

ANATOMY AND PATHOPHYSIOLOGY

Tricuspid atresia usually results in complete absence of the components of the tricuspid valve, with a smooth floor of the right atrium at the usual location of the tricuspid valve. In rare instances, tricuspid valve tissue and chordae are present, but the valve is imperforate. Associated right ventricular hypoplasia and pulmonary artery hypoplasia are proportional to the size of the ventricular septal defect and the degree of subpulmonary and pulmonary valve stenosis.

Systemic venous return from the inferior and superior venae cavae enters the right atrium and crosses the atrial septum, with resultant complete mixing of the systemic and pulmonary venous return in the left atrium. Pulmonary blood flow is supplied by left-to-right shunting through either the ductus arteriosus or the ventricular septal defect. The degree of systemic hypoxia is proportional to the relative systemic and pulmonary blood flow. Neonates with tricuspid atresia, small ventricular septal defect, and severe pulmonary stenosis have severely limited pulmonary blood flow and are ductal dependent. Those with large ventricular septal defects and no pulmonary stenosis have high pulmonary artery pressure and flow. When pulmonary artery resistance falls in these babies, pulmonary flow dramatically increases, and hypoxia is minimal. The babies are, in contrast, at risk for congestive heart failure as a result of excessive pulmonary blood flow and left ventricular volume loading.

ASSOCIATED DEFECTS

An atrial septal defect is essential for postnatal survival in all neonates with tricuspid atresia. Associated lesions have been reported with tricuspid atresia, including transposition of the great arteries, truncus arteriosus, and atrioventricular (AV) septal defect. The size of the ventricular septal defect is extremely important in neonates with the combination of tricuspid atresia and transposition of the great arteries. Those with restrictive ventricular septal defects have limited systemic blood flow and a high prevalence of associated coarctation of the aorta.

CLINICAL PRESENTATION

The typical neonatal presentation is cyanosis at the time of ductal closure and a murmur. Precordial activity is normal, and the second heart sound is single. There is a systolic ejection murmur arising from the subpulmonary and pulmonary valve stenosis. Absence of a harsh systolic murmur in a baby with tricuspid atresia suggests associated pulmonary atresia. A continuous murmur of ductal flow can be heard. If the ventricular septal defect is large, tachypnea, a left ventricular impulse, and a third heart sound develop during the first few days of life as the pulmonary vascular resistance falls. Hepatic enlargement is an important sign of a restrictive atrial septal defect and elevated right atrial pressures.

LABORATORY EVALUATION

The electrocardiogram is usually diagnostic in neonates with tricuspid atresia. The left anterior bundle conducts abnormally, and there is an abnormal superior and leftward frontal plane vector or axis. The right ventricular hypoplasia leads to diminished right ventricular forces and to an electrocardiographic diagnosis of left ventricular hypertrophy. The chest radiograph is nonspecific, although severely cyanotic neonates show decreased pulmonary vascularity. The echocardiogram (Fig. 45-14) defines the anatomy of the right ventricular OFT and the pulmonary artery, the presence of a ductus arteriosus, and a nonrestrictive atrial septal defect. Catheterization is rarely needed to assess pulmonary artery anatomy before surgery.

MANAGEMENT AND PROGNOSIS

Antegrade pulmonary flow across the ventricular septal defect may be adequate in the first months of life. It is usually possible to predict by echocardiogram when babies require a patent ductus arteriosus to maintain adequate arterial saturations. Balloon atrial septostomy is rarely necessary unless there is significant restriction at the atrial septal defect.

If the baby is ductal dependent or if hypoxia increases in the first month of life, a systemic-to-pulmonary shunt is necessary for providing adequate pulmonary blood flow and oxygenation. The long-term effect of left ventricular volume loading caused by systemic-to-pulmonary shunts and the risk for distortion of the pulmonary arteries must be considered; conversion to a bidirectional Glenn anastomosis is usually considered when an infant is between 3 and 6 months of age.[53] Some babies with well-balanced systemic and pulmonary flows can proceed directly to an early bidirectional Glenn operation[85] or to a Fontan operation at about 1 year of age. Among children who undergo the Fontan type of operation, those with tricuspid atresia have the best long-term prognosis, with a low prevalence of ventricular dysfunction, mitral regurgitation, arrhythmias, and systemic venous congestion (see Table 45-12 in Part 10).[96]

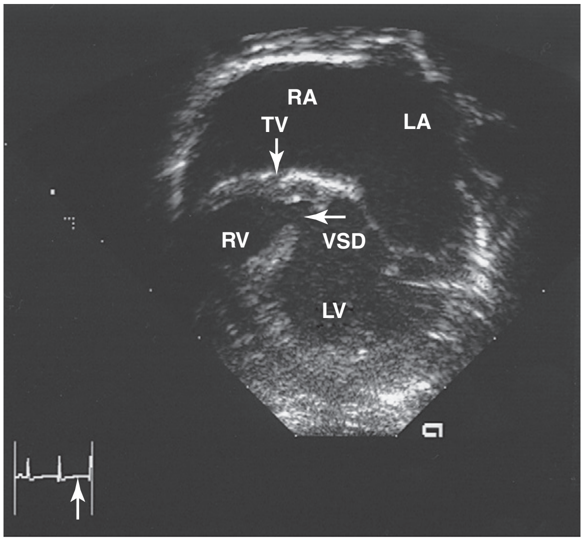

Figure 45–14. Apical four-chamber view of neonate with tricuspid atresia. Shown are a fibromuscular floor of the right atrium (TV), small ventricular septal defect (VSD), and hypoplastic right ventricle (RV). A large atrial septal defect permits free flow from the right atrium (RA) to the left atrium (LA) and into the left ventricle (LV).

Pulmonary Atresia with Intact Ventricular Septum and Critical Pulmonary Stenosis

ANATOMY AND PATHOPHYSIOLOGY

Neonatal critical pulmonary stenosis and pulmonary atresia share several important anatomic and pathophysiologic issues. The extent of right ventricular obstruction is profound, and the degree of right ventricular hypertrophy and dysfunction is high. Neonates with atresia of the pulmonary valve have a spectrum of disease from a thick membrane with hypoplastic annulus to well-developed sinuses with complete fusion of the cusps. Critical pulmonary stenosis lies at the latter end of the spectrum with a small amount of anterograde flow. There is an additional component of tricuspid valve and right ventricular inflow hypoplasia with hypoplasia of the trabecular portion of the body of the right ventricle. Despite the right ventricular hypoplasia and limited anterograde flow, the pulmonary arteries are usually well developed because of in utero ductal flow.

Systemic venous return largely crosses the atrial septum and mixes completely with the pulmonary venous return in the left atrium. Anterograde flow that does cross the tricuspid valve is ejected back into the atrium with minimal or no net anterograde flow. Right ventricular pressure exceeds left ventricular pressure. Flow to the pulmonary arteries is primarily by the ductus arteriosus.

ASSOCIATED DEFECTS

Fistulas between the right ventricle and the coronary arteries are the most critical associated lesions in this defect. They decompress the right ventricle by carrying desaturated systemic venous blood back to the aorta. They can also supply the coronary arteries, and in some cases they are the sole source of coronary flow with atresia of the coronary arteries at the aorta. The associated atrial septal defect is rarely restrictive in the neonatal period. Occasional neonates with pulmonary atresia have an associated mild degree of aortic stenosis or a bicuspid aortic valve.

CLINICAL PRESENTATION

Neonates with pulmonary atresia and an intact ventricular septum have severe hypoxia at the time the ductus arteriosus closes. A right ventricular impulse and a single second heart sound are present. A high-pitched holosystolic murmur of tricuspid regurgitation might be audible, or a murmur with systolic and diastolic components from flow in the coronary fistulas can be heard. The liver is enlarged because of the tricuspid regurgitation and right ventricular diastolic dysfunction. Fetal diagnosis frequently can identify the risk factors for subsequent interventional and surgical management, including tricuspid valve hypoplasia and coronary artery fistulas.[33]

LABORATORY EVALUATION

The electrocardiogram might be normal or might show a variable degree of right ventricular hypertrophy. Unlike neonates with tricuspid atresia, the neonates with pulmonary atresia might have a relatively normal right ventricular muscle mass despite a component of ventricular hypoplasia. The chest radiograph shows cardiomegaly caused by right atrial enlargement. The echocardiogram defines the degree of tricuspid valve and right ventricular hypoplasia. Color flow mapping can detect patency of the valve, and the right ventricular pressure can be estimated by the tricuspid regurgitation velocity. Flow in coronary fistulas may be seen on the epicardium and within the myocardium by color flow mapping. Fistulas must also be suspected if there is anterograde tricuspid valve flow and no tricuspid regurgitation. Cardiac catheterization is usually indicated to assess coronary flow and consider balloon dilation of the pulmonary valve.

MANAGEMENT AND PROGNOSIS

Prostaglandin E_1 therapy is essential in maintaining ductal patency. Careful assessment of the individual baby's anatomy and physiology provides a framework for interventional and surgical management.[6] Balloon pulmonary valvuloplasty is feasible in all babies with even a tiny orifice in the pulmonary valve, and novel techniques, including radiofrequency ablation to open the valve in the catheterization laboratory, can be considered (see "Neonatal Interventional Catheterization" in Part 10).[4]

If interventional catheterization is unsuccessful, surgical valvotomy is indicated unless there is clear dependence of the coronary flow on the right ventricle. In that circumstance, decompression of the right ventricle could result in coronary hypoperfusion, so that a systemic-to-pulmonary shunt is a better option.

In babies with successful surgical or interventional valvotomies, right ventricular growth is possible, and biventricular circulation can be expected.[41,46]

Severe tricuspid hypoplasia or right ventricle-dependent coronary circulation is an indication for a long-term Glenn and Fontan approach to separate the systemic and pulmonary circulations.[38] Babies who have right ventricular hypoplasia might also be candidates for a bidirectional Glenn operation combined with closure of the atrial septal defect. This procedure directs the inferior vena caval blood across the hypoplastic tricuspid valve and uses the right ventricle (see Table 45-12 in Part 10).

Ebstein Anomaly

ANATOMY AND PATHOPHYSIOLOGY

The tricuspid valve annulus is displaced downward into the right ventricle and the tricuspid valve leaflets are tethered to the wall in Ebstein anomaly. The area of the right ventricle between the true and functional annulus is thin walled, or "atrialized." The extent of displacement is variable; however, in severe forms, the displacement of the valve could also obstruct the right ventricular OFT.

The valve could have both impaired filling and regurgitation, leading to elevated right atrial pressures and right-to-left shunt at the atrial level. The degree of atrial-level shunting usually parallels the severity of the malformation of the valve. Right ventricular pressure is low, and the functional volume of the right ventricle is diminished.

ASSOCIATED DEFECTS

Ebstein anomaly usually occurs as an isolated defect or in association with an atrial septal defect or patent foramen ovale. Occasional patients with coarctation of the aorta are described. Wolff-Parkinson-White syndrome or concealed bypass tracts are found in about 20% of patients. If there is associated L-transposition of the great arteries, the Ebstein malformation still occurs in the anatomic right ventricle. In these babies, AV valve regurgitation and ventricular dysfunction may be severe.

CLINICAL PRESENTATION

At presentation, neonates with severe Ebstein malformation have severe cyanosis caused by atrial-level right-to-left shunting. They have a diffusely active precordium, multiple systolic clicks, and a low-frequency holosystolic murmur of tricuspid regurgitation. If the malformation is mild, the diagnosis could be suggested by a click or during evaluation for neonatal supraventricular tachycardia.

LABORATORY EVALUATION

The electrocardiogram of babies with severe Ebstein malformation shows an RSR′S′ pattern across the right side of the chest, suggesting right ventricular dilation. The chest radiograph shows marked cardiomegaly caused by right atrial dilation. The area of the right atrium and of the atrialized right ventricle has been a useful sign of severity and outcome.[108]

MANAGEMENT AND PROGNOSIS

Mild forms of Ebstein anomaly require no specific treatment, and the infants generally do well.[95a] The severely affected neonate might be ductal dependent and might have no anterograde flow through the right ventricle.[108] Maintaining patency of the ductus arteriosus with prostaglandin E_1 can be useful in the short term; however, ductal flow into the pulmonary artery can make anterograde flow more difficult, and the right ventricle can fill by pulmonary regurgitation. In severe Ebstein anomaly, measures to lower the pulmonary vascular resistance, including nitric oxide and several attempts to wean the infant from prostaglandin E_1, might be necessary before anterograde flow becomes established.[9] Brief support with extracorporeal membrane oxygenation to facilitate this transition has been successful in a few babies. Surgical repair or replacement of the valve is feasible in older children who have symptomatic disease but has not been useful in neonates. Either surgical exclusion of the right ventricle, with plans for a long-term Fontan repair, or transplantation might be the only alternative for the neonate with severe, persistent cyanosis.[56]

CYANOTIC DEFECTS: COMPLETE MIXING

Total Anomalous Pulmonary Venous Connection

ANATOMY AND PATHOPHYSIOLOGY

Total anomalous pulmonary venous connection comprises a group of defects in which the pulmonary veins enter the right side of the heart rather than the left atrium. The common sites of anomalous connection to the pulmonary veins are to the superior vena cava through the innominate vein, to the right atrium or coronary sinus, and to the inferior vena cava through the portal venous system. The veins connecting the pulmonary venous confluence to the right atrium are nearly always obstructed as they pass through the liver. In a smaller fraction of newborn infants, the vertical vein connecting the pulmonary venous confluence to the innominate vein is compressed as it passes between the left pulmonary artery and the left bronchus. If the pulmonary veins do not share a common confluence, the pulmonary venous connection could be mixed with veins from different lung segments draining through connections above and below the diaphragm.

Pulmonary venous return mixes completely with systemic venous return in the right atrium. Blood flow to the left side of the heart is entirely by shunting from the right atrium to the left atrium through the foramen ovale. In the absence of pulmonary venous obstruction, pulmonary blood flow is increased and hypoxia is mild. In contrast, if the pulmonary venous connection is obstructed as it passes through the mediastinum or liver, there is pulmonary venous hypertension with pulmonary edema and diminished pulmonary blood flow. The combination of decreased pulmonary blood flow and impaired pulmonary function caused by edema results in profound systemic hypoxia.

ASSOCIATED DEFECTS

An atrial septal defect is essential for postnatal survival and is rarely obstructed in the neonatal period. At the time of presentation, neonates often have a patent ductus arteriosus. Left heart defects, transposition of the great arteries, and tetralogy of Fallot have been reported with total anomalous pulmonary venous connection. The most common association is in neonates with asplenia syndrome and complex single ventricular anatomy. Total anomalous pulmonary venous connection occurs in a large portion of these babies, including those with pulmonary atresia.

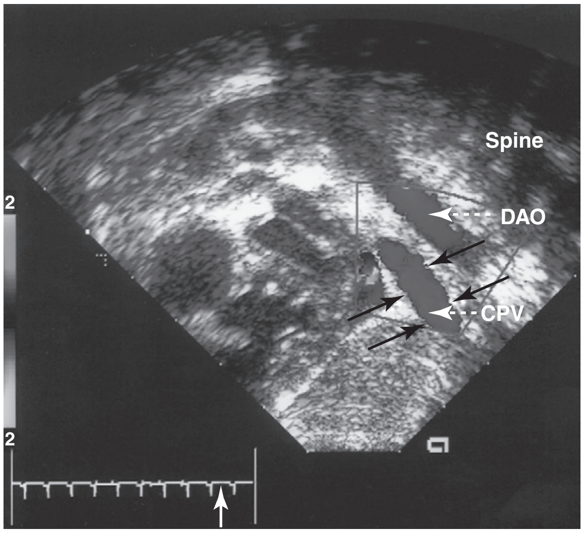

Figure 45–15. Subcostal Doppler echocardiogram illustrates anatomy and blood flow of a neonate with a total anomalous pulmonary venous connection below the diaphragm. In this study, the spine is on the *right*. Superior mediastinal structures are at the *top*, and the liver is at the *bottom* of the frame. Structures shown, from posterior to anterior (*left* of frame), are descending aorta (DAO), common pulmonary vein and descending vertical vein (CPV), small left ventricle, and dilated right ventricle. Blood flow is from superior to inferior in these views. Blood flow (outlined by *black arrows*) in the dilated CPV is going below the diaphragm, where it enters the liver and returns to the inferior vena cava.

CLINICAL PRESENTATION

The clinical presentation of the newborn infant with total anomalous pulmonary venous connection is variable. Cyanosis and respiratory distress are usually limited to babies with obstructed pulmonary venous connections. These babies have a right ventricular impulse, a single second heart sound, and no murmur. In most neonates without pulmonary venous obstruction, tachypnea and right ventricular heave gradually develop because of the increased right ventricular and pulmonary blood flow. Pulmonary artery pressure is not necessarily elevated, and the second heart sound could be split. A systolic ejection murmur at the upper left sternal border with radiation to the lungs is usually present because of the increased flow, but it is not necessarily harsh and obviously pathologic.

LABORATORY EVALUATION

The electrocardiogram in the neonatal period is normal. Pulmonary edema seen on the chest radiograph is highly suggestive of pulmonary venous obstruction. Dilated mediastinal veins can give an appearance of fullness (snowman sign) to the superior mediastinum, although in neonates, this is usually masked by the thymus. The echocardiogram (Fig. 45-15) should demonstrate the entry of each pulmonary vein into the confluence and define the course of the drainage of the confluence. Sites of venous obstruction are seen by imaging and turbulent flow by color flow mapping and Doppler imaging.

The size of the individual pulmonary veins and of the confluence should be measured because pulmonary venous diameters less than 2 mm are associated with a poor prognosis.[49] Evidence of restriction of the atrial septal defect is important to recognize. Cardiac catheterization is helpful in further delineating the venous anatomy if it is uncertain by echocardiography, especially in newborn infants with possible mixed pulmonary venous connection patterns.

MANAGEMENT AND PROGNOSIS

Unobstructed total anomalous pulmonary venous connection requires little specific medical management. Neonates with evidence of restrictive atrial septal defects should be started on a regimen of prostaglandin E_1 therapy to maintain patency of the ductus arteriosus and ensure systemic blood flow. Neonates with pulmonary venous obstruction are profoundly hypoxic and require significant respiratory and metabolic support. Extracorporeal membrane oxygenation has been used as a bridge to total repair (see Chapter 44, Part 8).

Elective repair—anastomosis of the common pulmonary venous confluence to the left atrium—in the first month of life is appropriate for neonates with unobstructed flow. Urgent surgery is essential for those with pulmonary venous obstruction. Postoperative pulmonary artery hypertension and pulmonary vascular reactivity is most troublesome in neonates with preoperative pulmonary venous obstruction. The long-term prognosis is excellent except in those neonates with hypoplastic pulmonary veins[49] or single ventricle anatomy.[40] Recurrent or persistent pulmonary venous obstruction at the anastomosis or within the veins is difficult to treat either by surgery or interventional catheterization.[59] Arrhythmias and a poor chronotropic response to exercise have been reported in some patients after surgery.[101]

Truncus Arteriosus

ANATOMY AND PATHOPHYSIOLOGY

In truncus arteriosus, there is a common origin of aorta and pulmonary artery from a single semilunar valve. The relationship of the origin of the pulmonary arteries from the truncus is variable. In type 1 truncus, the pulmonary arteries arise from the left lateral aspect of the truncus, with a short main pulmonary artery. In type 2 truncus, there is no main pulmonary artery, and the origin of the right and left pulmonary arteries is directly from the posterior or lateral aspect of the truncus arteriosus. In type 3 truncus, either the right or left pulmonary artery is absent, or it arises from the ductus arteriosus, and a large subarterial ventricular septal defect with deficiency of the conal portion of the septum produces overriding of the truncus over the ventricular septum.

The pulmonary artery pressure is comparable to aortic pressure, and diastolic pressure is decreased in the aorta because of the nonrestrictive connection with the low-impedance pulmonary vascular bed. The systemic and pulmonary venous returns completely mix in the truncus. Partitioning of the flow to the pulmonary artery and the aorta is determined by the relative systemic and pulmonary vascular resistance. In the first days of life, as the pulmonary vascular resistance falls, there is a relative increase in pulmonary blood flow. The pulmonary blood flow increases with a relatively constant systemic blood flow, and the arterial oxygen saturation in the truncus increases. The hemodynamic consequences are increased pulmonary arterial and left ventricular flow with resultant pulmonary venous hypertension and left atrial and left ventricular dilation.

ASSOCIATED DEFECTS

Truncal valve stenosis or regurgitation is present in about 20% of neonates. The truncal valve can have two, three, or four cusps, with a variable degree of thickening or abnormal coaptation. Truncal stenosis places an additional pressure load on both the right and left ventricles. Truncal regurgitation often increases left ventricular stroke volume, although truncal regurgitation into the right ventricle can occur. Unilateral or bilateral branch pulmonary artery stenosis occurs in 10% of children, reducing both the pulmonary artery pressure and the flow to the affected lung. Atresia of the origin of a branch pulmonary artery usually causes the vascular supply of the lung to be from aortic to pulmonary collateral vessels. Coronary artery stenosis and malposition are rare but surgically important variations.[1] These include origin of the left coronary artery in the proximal pulmonary artery. A right aortic arch is found in 15% to 25% of neonates with truncus. A small number of neonates have truncus arteriosus and aortic arch interruption, with a small ascending aorta branching into the innominate artery and the left carotid artery. The left subclavian artery and the descending aorta come from the truncus through a large patent ductus arteriosus.

CLINICAL PRESENTATION

The neonatal presentation of uncomplicated truncus arteriosus can be subtle. Mild tachypnea or cyanosis might be the only symptom. The left ventricular impulse increases as the pulmonary vascular resistance falls. Neonates with abnormal truncal valves have a systolic ejection click. The second heart sound is single, and there may be an apical third heart sound. The pulses are bounding, and the pulse pressure is wide with decreased diastolic pressure. A vibratory systolic ejection murmur from increased truncal valve flow and a mid-diastolic murmur from increased mitral valve flow could also be present. A harsh systolic ejection murmur and a blowing early diastolic murmur suggest associated truncal valve stenosis and regurgitation. Early signs of congestive heart failure suggest in utero pressure and volume loading resulting from truncal valve stenosis and regurgitation. Poor perfusion and decreased leg pulses indicate ductal narrowing if there is associated arch interruption.

LABORATORY EVALUATION

The electrocardiogram is usually normal in the neonatal period. ST-T segment changes suggest poor coronary perfusion caused by low diastolic pressures. Left ventricular hypertrophy can be seen in neonates with in utero truncal stenosis and regurgitation. The chest radiograph identifies the side of the aortic arch.

After the initial diagnosis, echocardiography must be directed to the definition of associated defects, including those of the truncal valve, branch pulmonary arteries, arch anatomy, and coronary arteries. The size of the thymus must also be defined. Cardiac catheterization is reserved only for neonates in whom the presence of associated defects is uncertain.

Pulse oximetry and arterial oxygen saturation are usually about 85%. Lower saturations are seen before the pulmonary vascular resistance falls or if either branch pulmonary artery stenosis or pulmonary dysfunction caused by edema is present. Acidosis suggests decreased systemic blood flow and is most commonly seen in neonates with associated truncal stenosis and regurgitation or arch interruption. The serum calcium concentration can fall in neonates with associated DiGeorge anomaly. All neonates with truncus arteriosus should be examined for microdeletion of chromosome 22.

MANAGEMENT AND PROGNOSIS

Supplemental oxygen can decrease pulmonary vascular resistance and should be avoided unless severe hypoxia and pulmonary edema are present. Tachypnea caused by increased pulmonary flow often responds to digoxin and furosemide. Medical management of neonates with significant truncal stenosis or regurgitation is usually unsuccessful, and their hemodynamic difficulties can be further complicated by tracheal compression caused by truncal dilation. Hypocalcemia resulting from hypoparathyroidism should be corrected.

Truncus arteriosus is routinely repaired in the first month of life and often in the neonatal period. The ventricular septal defect is closed, and a connection is made from the right ventricle to the pulmonary artery, usually with a homograft. Postoperative pulmonary hypertensive crises are minimized by repair in the first month of life. Associated defects, including truncal valve stenosis, arch interruption, coronary abnormalities, and branch pulmonary artery atresia, increase risk but do not preclude repair.[102] If truncal stenosis and regurgitation are severe, homograft truncal valve replacement is necessary to provide a competent neoaortic valve.[17]

The long-term prognosis is excellent for children with truncus arteriosus. Homograft replacement is required by age 5 years in about 20% of patients.[43] Neoaortic valve stenosis and regurgitation gradually worsen and can require repair or replacement of the valve in 25% of patients.[44] Ventricular dysfunction and arrhythmias are not expected.

CYANOTIC DEFECTS: VARIABLE PHYSIOLOGY

Single Ventricle

The anatomic variability of neonates with a single ventricle is broad. Two forms of single ventricle—tricuspid atresia and hypoplastic left heart syndrome—are discussed in separate sections.

A methodical segmental approach to venous, atrial, ventricular, and arterial size and connections does permit accurate anatomic diagnosis. Connections between the atria and the ventricles can be concordant or discordant. Similarly, the ventricular-arterial relationship may be normal, or D-transposition or L-transposition might be present. The hypoplastic ventricle can be either the anatomic right or anatomic left ventricle. Several pathophysiologic principles unite the defects and are the foundation of effective neonatal management.

Complete mixing of the systemic and pulmonary venous blood flow occurs in all forms of single ventricle. The cause can be anomalous pulmonary venous return, atresia of one of the AV valves with atrial-level shunting, or double inlet of the mitral and tricuspid valves into a single ventricle. Regardless of the site of mixing, the oxygen saturation in the ventricle and the aorta is determined by the relative systemic and pulmonary blood flow. Babies with defects involving pulmonary stenosis and restricted blood flow have low arterial oxygen saturation, and those with unrestricted pulmonary flow have relatively higher oxygen saturation.

It is particularly important to recognize babies in this latter group because they are sensitive to oxygen as a pulmonary vasodilator, and supplemental oxygen can therefore markedly increase pulmonary blood flow and reduce systemic blood flow.

The origin of one of the great arteries is usually from a hypoplastic outlet chamber. Especially in babies with L-transposition of the great arteries, hypoplastic right ventricle, and double-inlet left ventricle, the bulboventricular foramen (ventricular septal defect) could be restrictive.[68] The result, subaortic obstruction in utero and postnatally, is often associated with coarctation of the aorta. It is particularly important to recognize this defect before placing a pulmonary artery band to reduce pulmonary flow and pressures. Banding can hasten the natural progression of the subaortic obstruction or cause ventricular dysfunction because of the combined afterload of the band and the subaortic narrowing. A Damus-Kaye-Stansel operation or a modification of the Norwood operation anastomoses the main pulmonary artery to the ascending aorta and could be needed in the first month of life to bypass the subaortic obstruction.[21,26,71] Pulmonary blood flow is provided by a systemic-to-pulmonary shunt in a fashion similar to the Norwood procedure. Other babies could have an arterial switch operation to relieve the obstruction (see Table 45-12 in Part 10).[58]

Babies with hypoxia caused by pulmonary stenosis and single ventricle are managed with a shunt in the neonatal period. Although a neonatal bidirectional Glenn procedure would be ideal, high pulmonary vascular resistance makes a venous-to-pulmonary artery connection prone to high systemic venous pressures. For babies with excessive pulmonary flow, a pulmonary artery band might be needed for several months before the bidirectional Glenn procedure can be performed.

The most challenging group of babies with single ventricle are those with pulmonary atresia, discontinuous pulmonary arteries, collateral supply of pulmonary blood flow, and pulmonary venous obstruction. These babies often have asplenia syndrome, and because of their unfavorable pulmonary artery architecture and venous obstruction, they are poor long-term candidates for the Fontan approach to single ventricle (see Table 45-12 in Part 10).

Long-term surgical planning for babies with single ventricle must begin in the neonatal period. Because they eventually must have a Fontan procedure, careful attention to the preservation of pulmonary arterial anatomy and low resistance is essential. Shunts from the systemic to the pulmonary circulation must not distort the pulmonary arteries or excessively volume-load the ventricle. Conversion of the shunt to a bidirectional Glenn procedure at as early as 3 months of age improves ventricular volume loading and ensures low pulmonary artery pressures.[2,85] Relief of subaortic obstruction improves systemic blood flow and ventricular diastolic function.[21,26,71] Any degree of pulmonary venous obstruction caused either by left AV valve stenosis or anomalous pulmonary venous return must be repaired before the Glenn procedure, and repair might be needed when there is a shunt from the systemic to the pulmonary artery circulation.

Double-Outlet Right Ventricle

ANATOMY AND PATHOPHYSIOLOGY

In double-outlet right ventricle, the aorta and the pulmonary artery arise side by side from the right ventricle. The pulmonary valve is to the left, the aortic valve is to the right, and the semilunar valves are at the same level. This defect is caused by a bilateral subarterial conus, which also distorts the normal aorta to mitral valve fibrous continuity. The location of the ventricular septal defect defines the type of double-outlet right ventricle. Babies with a subaortic ventricular septal defect have streaming from the left ventricle to the aorta, and the pathophysiology is similar to that in babies with a large ventricular septal defect. Those with subpulmonary ventricular septal defect, Taussig-Bing malformation, have streaming from the left ventricle into the pulmonary artery and have a circulation similar to transposition of the great arteries with ventricular septal defect.[89] Less commonly, the ventricular septal defect could be doubly committed below both arteries or remote in the muscular septum.

ASSOCIATED DEFECTS

The most important associated defect is pulmonary and subpulmonary stenosis. The additional obstruction to pulmonary blood flow in double-outlet right ventricle with subaortic ventricular septal defect causes a malformation similar to tetralogy of Fallot. Similarly, babies with a subpulmonary ventricular septal defect and pulmonary stenosis have the combination of transposition flow patterns with diminished pulmonary flow and pressure. The ventricular septal defect could be restrictive, leading to suprasystemic right ventricular pressures.

CLINICAL PRESENTATION

At presentation, double-outlet right ventricle usually is manifested by neonatal cyanosis or murmurs. If there is a subaortic ventricular septal defect and no pulmonary stenosis, the initial examination could reveal only a mildly hyperactive precordium and a single second heart sound; however, congestive heart failure develops in the first few weeks of life.

LABORATORY EVALUATION

The electrocardiogram and chest radiograph are nonspecific. The most important echocardiographic goal is to define the size and location of the ventricular septal defect relative to the great arteries.

MANAGEMENT AND PROGNOSIS

Neonatal repair of double-outlet right ventricle with a subpulmonary ventricular septal defect uses the arterial switch approach to move the aorta closer to the ventricular septal defect and permit an intraventricular baffle from the left ventricle to the neoaorta.[18,89] If there is a subpulmonary ventricular septal defect and pulmonary stenosis or atresia, the left ventricular outflow is baffled to the aorta. The pulmonary artery is removed from the heart and connected to the body of the right ventricle with a conduit. Babies with subaortic ventricular septal defect are managed similarly to those with tetralogy of Fallot or uncomplicated ventricular septal defect.[18]

SYSTEMIC HYPOPERFUSION WITH CONGESTIVE HEART FAILURE

Aortic Stenosis

ANATOMY AND PATHOPHYSIOLOGY

Aortic valve disease is a spectrum of malformations from an isolated bicuspid aortic valve to critical aortic valve stenosis with poorly differentiated valve cusps. Aortic stenosis has an in utero hemodynamic impact, and neonates have left ventricular hypertrophy, which generates the increased left ventricular pressure to overcome the obstruction. Mild to moderate obstruction is well tolerated in utero and postnatally with maintenance of good left ventricular systolic function. However, with severe obstruction, the left ventricle can develop significant dilation and dysfunction. It is the group of neonates with this latter defect who might be dependent on the ductus arteriosus at birth. In these neonates, a significant portion of the systemic blood flow is supplied by shunting across the ductus arteriosus from the pulmonary artery to the aorta. In a steady state, this blood flow comes from atrial-level left-to-right shunting, which is enhanced because of high left ventricular diastolic pressures. The physiology in these babies is similar to that in babies with hypoplastic left heart syndrome.

ASSOCIATED DEFECTS

See also “Multiple Left Heart Defects,” later.

Mild aortic stenosis accompanied by a large patent ductus arteriosus might present a challenging problem in an assessment of the aortic valve disease. Because the flow past the aortic valve is increased by the left-to-right shunt at the ductus, the pressure gradient across the aortic valve is exaggerated. Reassessment after spontaneous, surgical, or temporary balloon ductal closure might be needed to determine the true severity of the aortic valve obstruction.

Aortic regurgitation is rare in neonates with aortic valve stenosis. The presence of a diastolic decrescendo murmur of aortic regurgitation should raise the possibility of a tunnel from the left ventricle to the aorta.[67] This defect is just outside the aortic annulus, which is an additional pathway for ejection during systole and a site of regurgitation in diastole. The aortic valve might also be abnormal. Careful evaluation of the site of regurgitation by color flow mapping usually identifies this defect.

Aortic root dilation is found even with mild aortic stenosis. There may be a component of supravalvular aortic stenosis just distal to the aortic sinuses in these babies. Babies with Williams syndrome have more diffuse supravalvular aortic stenosis beyond the sinotubular junction.[55] Diffuse aortic root hypoplasia usually is a sign of associated coarctation of the aorta or left heart hypoplasia with severe aortic valve stenosis.

CLINICAL PRESENTATION

A bicuspid aortic valve can cause a systolic ejection click but no murmur in a neonate with no symptoms. Commonly, the defect is not detected until several years of age. Mild or moderate aortic stenosis causes a systolic ejection click and a harsh systolic ejection murmur that is audible shortly after birth. In the neonate, the murmur can be difficult to differentiate from a murmur caused by pulmonary stenosis, although radiation to the neck instead of the back should suggest aortic stenosis. The pulses and precordial activity are normal in these babies. With increasing severity of aortic stenosis, the murmur becomes louder, but the pulse volume can decrease.

Critical aortic stenosis has a clinical presentation similar to that of hypoplastic left heart syndrome. Poor feeding and respiratory distress caused by decreased cardiac output and pulmonary edema are frequent symptoms. There is a right ventricular heave, no click, and a soft systolic ejection murmur. If the ductus arteriosus is patent, the pulses are palpable, but with ductal narrowing, the pulses diminish. Right ventricular volume and pressure overload cause elevated right atrial pressures and hepatomegaly. Shock, acidosis, and multisystem failure occur with ductal closure.

LABORATORY EVALUATION

Because the severity of neonatal aortic stenosis is difficult to assess clinically, careful noninvasive assessment is essential. The electrocardiogram is usually normal, although occasional neonates with severe stenosis and in utero left ventricular dilation and hypertrophy have left ventricular hypertrophy on the electrocardiogram. The chest radiograph is most useful in detecting pulmonary edema. The echocardiogram (Fig. 45-16A) must be used to assess the anatomy to the aortic valve, the pressure gradient estimated by Doppler imaging (see Fig. 45-16B), and the presence of associated defects of the left side of the heart. Any indication of right-to-left shunting at the ductal level must be assumed to indicate either severe stenosis or associated coarctation of the aorta or mitral stenosis. Pulse oximetry or arterial blood gas determination in the right arm and the umbilical artery or leg also suggests right-to-left ductal shunting. Arterial blood gas or electrolyte measurements can be followed as an indication of tissue perfusion and renal function.

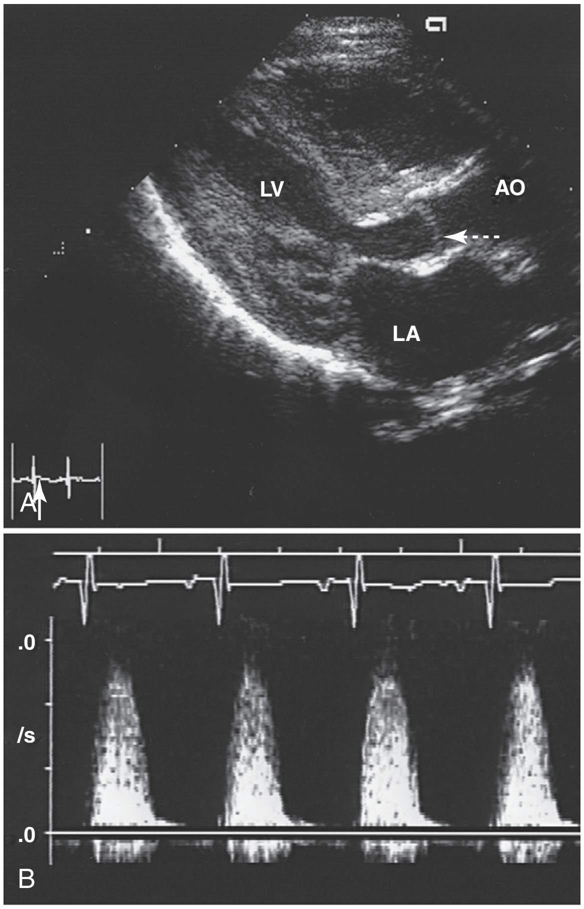

Figure 45–16. **A**, This 1-week-old infant was referred for evaluation of a systolic murmur. The echocardiogram, in long-axis view, shows thickened, domed aortic valve (*arrow*) and dilated ascending aorta (AO). There is left ventricular (LV) hypertrophy and hyperdynamic systolic function. LA, left atrium. **B**, Continuous-wave Doppler from the suprasternal notch shows left ventricular outflow tract velocity of 4.6 m/sec (85 mm Hg peak systolic gradient). Each mark on the scale on the left of frame is a velocity of 2 m/sec. Full scale is 6 m/sec. Mean velocity predicted gradient of 58 mm Hg, which is comparable to the systolic gradient measured before successful aortic balloon valvuloplasty.

MANAGEMENT AND PROGNOSIS

Neonatal bicuspid aortic valve or mild aortic stenosis without associated defects is well tolerated and requires no specific medical treatment except prophylaxis for bacterial endocarditis. Moderate and severe aortic stenosis can progress during the first few months of life, and careful follow-up is essential. Any indication of congestive heart failure or ventricular dysfunction in an infant with severe aortic stenosis is an indication for balloon or surgical valvotomy. Critical aortic stenosis is a neonatal emergency and continues to result in morbidity and death.

Success rates with neonatal balloon aortic valvuloplasty have been good, although residual or recurrent stenosis and aortic regurgitation are common (see “Neonatal Interventional Catheterization” in Part 10).[39,70] Valvotomy or transventricular dilation remains an alternative as a primary procedure or if balloon valvuloplasty is unsuccessful.[72] Either approach has limitations in neonates with marked annular hypoplasia, unicuspid aortic valve, associated subaortic obstruction, and ventricular hypoplasia or dysfunction. For these neonates, a Norwood approach to bypass the left ventricle or an aortic root enlargement and pulmonary autograft replacement[77] might be a more suitable long-term solution (see Table 45-12 in Part 10). The selection of babies with borderline criteria for a two-ventricle approach remains challenging.[22,25]

Coarctation of the Aorta and Aortic Arch Interruption

ANATOMY AND PATHOPHYSIOLOGY

Aortic arch obstruction occurs at several predictable levels distal to the aortic root. Coarctation of the aorta is the most common and consists of narrowing in the juxtaductal region distal to the left subclavian artery. It can be associated with transverse aortic and isthmic hypoplasia. Aortic arch interruption can occur at the same site (type A), but in aortic arch interruption, there is complete discontinuity of the aorta between the left subclavian artery and the insertion of the ductus arteriosus into the descending aorta. Type B aortic arch interruption is between the left carotid artery and the left subclavian artery. The origin of the right subclavian artery from the aorta distal to the ductus arteriosus can be found with either coarctation of the aorta or aortic arch interruption.

Coarctation of the aorta presents an increased afterload to the left ventricle, resulting in left ventricular hypertrophy and hypertension. Dilated collateral vessels develop between the branches of the ascending aorta and the descending aorta distal to the coarctation to carry flow to the distal aorta. In some neonates with coarctation of the aorta and in all neonates with aortic arch interruption, the severity of the obstruction results in either left ventricular failure or inadequate lower body perfusion at the time of ductal closure. The ductus arteriosus is critical to survival in these babies because it can perfuse the descending aorta from the pulmonary artery. The right-to-left ductal-level shunting is balanced by an equal volume of atrial- or ventricular-level left-to-right shunting. This left-to-right shunt increases the oxygen saturation in the main pulmonary artery and the descending aorta. In some babies with juxtaductal coarctation of the aorta, right-to-left shunting is not significant; however, closure of the ductus arteriosus can further narrow the site of coarctation and cause poor distal perfusion.

ASSOCIATED DEFECTS

Coarctation of the aorta is a frequent component of diffuse left-heart disease (multiple left-heart defects). Bicuspid aortic valve and ventricular septal defect are common isolated associated defects. Aortic arch interruption is invariably associated with ventricular septal defect, aortic pulmonary window, truncus arteriosus, or transposition of the great arteries. The ventricular septal defect can be malaligned and can cause subaortic obstruction. Partial or complete DiGeorge syndrome or microdeletion of chromosome 22 is found in association with aortic arch interruption and occasionally in association with coarctation of the aorta.

CLINICAL PRESENTATION

Symptom-free newborn infants who have diminished leg pulses on a routine discharge examination have mild coarctation of the aorta and usually no associated aortic valve stenosis or septal defects. Early signs and symptoms of congestive heart failure should raise concern about associated defects. Careful palpation of all pulses, including the neck (Table 45-6), can provide valuable anatomic data. The pulse discrepancy should be confirmed by blood pressure measurement in both arms and both legs. Precordial hyperactivity, a single second heart sound, a gallop rhythm, and hepatomegaly indicate significant obstruction or associated defects. Holosystolic murmurs suggest either a ventricular septal defect or mitral regurgitation. The typical systolic murmur, well localized to the back, which is heard in older children with coarctation of the aorta, is not usually heard in neonates.

LABORATORY EVALUATION

The electrocardiogram and chest radiograph of a neonate with coarctation of the aorta or aortic arch interruption are usually normal. Significant cardiomegaly suggests associated lesions or ventricular dilation or dysfunction after the ductus arteriosus closes. Echocardiography (Fig. 45-17) can define the arch with considerable accuracy, although predicting the severity of the coarctation with the ductus arteriosus open is occasionally difficult. Right-to-left ductal shunting is an important sign of significant obstruction. Transverse arch hypoplasia, especially with a long segment between the left carotid and left subclavian arteries, suggests a significant coarctation of the aorta. Pulse oximetry and arterial blood gas measurements in the upper and lower extremities can confirm ductal shunting and perfusion.

MANAGEMENT AND PROGNOSIS

Uncomplicated coarctation of the aorta can be repaired electively in early childhood. Indications for repair in early infancy are significant hypertension or any sign of ventricular dysfunction. Surgical repair with end-to-end anastomosis remains the primary approach in many centers. Balloon angioplasty of native coarctation of the aorta can also be considered (see "Neonatal Interventional Catheterization" in Part 10).

Neonates with congestive heart failure or signs of poor perfusion must be treated with prostaglandin E_1 to maintain or restore ductal patency. All neonates with aortic arch interruption must have primary surgical repair of both the aortic arch abnormality and associated defects. Long-term results with interrupted aortic arch and aortopulmonary window or ventricular septal defect are good; however, recurrent arch obstruction and subaortic stenosis are frequent problems.[69] Mortality and morbidity in newborns with interrupted aortic arch and truncus arteriosus remain significant. Similarly, neonates with coarctation of the aorta and a large ventricular septal defect undergo primary repair.[51,83] Those with significant arch hypoplasia might require mobilization of the descending aorta to provide enough tissue to relieve the obstruction.[24]

Severe coarctation of the aorta without hemodynamically important associated defects is repaired through the left side of the chest. Balloon angioplasty of native coarctation of the aorta is usually reserved for older children but might be useful in the treatment of selected neonates.[78,90a] Postoperative systemic hypertension, the hallmark of coarctation in older children, is rare in neonates. Long-term growth of the repair might be an issue in up to 30% of babies, with premature infants having a higher risk.[52] Balloon angioplasty has been effective in the treatment of recurrent coarctation.

TABLE 45–6 Pulses or Blood Pressure

Site	Coarctation or Interruption Distal to Left Subclavian Artery	Interruption Distal to Left Carotid Artery	Coarctation with Aberrant Right Subclavian Artery	Interruption Distal to Left Carotid Artery with Aberrant Right Subclavian Artery	Aortic Stenosis, Aortic Atresia, and Cardiomyopathy
Right arm	+	+	–	–	–
Neck	+	+	+	+	–
Left arm	+	–	+	–	–
Legs	–	–	–	–	–

+, normal; –, diminished.

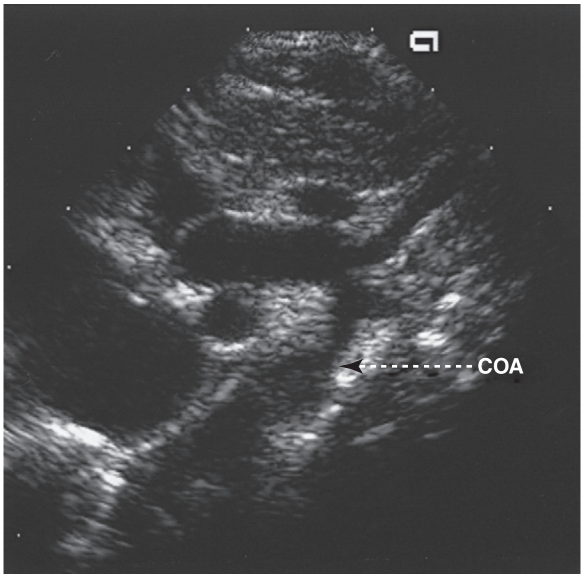

Figure 45–17. Echocardiogram from the suprasternal notch, demonstrating coarctation of the aorta (COA) just distal to the left subclavian artery. Mild hypoplasia of the transverse arch and poststenotic dilation of descending aorta are seen. Doppler study of this 1-week-old infant showed continuous high-velocity flow at the coarctation site and no evidence of patent ductus arteriosus.

Hypoplastic Left Heart Syndrome

Before 1980, no effective palliation was available for hypoplastic left heart syndrome. The Norwood operation[75] and the application of cardiac transplantation to the neonate[14] with hypoplastic left heart syndrome have afforded new hope to the families of newborn infants with this lethal heart defect. The advances in both of these approaches have brought us much closer to the reality of an acceptable quality and duration of life.

ANATOMY AND PATHOPHYSIOLOGY

Hypoplastic left heart syndrome includes aortic valve atresia, mitral valve atresia, and severe left ventricular and proximal aortic hypoplasia. Aortic coarctation is often associated.[64] Left ventricular endocardial fibroelastosis or infarction can develop because of in utero subendocardial ischemia. Coronary artery abnormalities have been recognized but have uncertain impact on long-term myocardial function.[11] Variations on this classic anatomy include degrees of aortic and mitral valve stenosis and left ventricular and aortic hypoplasia.

In hypoplastic left heart syndrome, the entire systemic circulation is supplied by blood from the main pulmonary artery that crosses the ductus arteriosus and enters the aorta. Flow from the ductus arteriosus goes retrograde to the ascending aorta and anterograde to the descending aorta. In utero, with high pulmonary vascular resistance, this circulation provides excellent organ perfusion, and the growth of the fetus is often normal. After birth, even when pulmonary vascular resistance falls and pulmonary blood flow increases, right ventricular output is usually adequate to supply both the systemic and the pulmonary circulations. However, closure of the ductus arteriosus dramatically alters this balance and results in profound systemic hypoperfusion with acidosis and multisystem organ failure.

ASSOCIATED DEFECTS

The most important associated defects are anomalies of pulmonary venous return[95] or of the right aortic arch. Occasional neonates with aortic atresia have a normal mitral valve and normal left ventricular size because of an associated ventricular septal defect. The absence of an atrial septal defect creates severe in utero pulmonary venous hypertension and limits pulmonary blood flow after birth.[35] Central nervous system anomalies, including absent corpus callosum, might be more common in babies with hypoplastic left heart syndrome.[36]

CLINICAL PRESENTATION

In utero diagnosis has dramatically changed the presentation of neonates with hypoplastic left heart syndrome. For families who have early prenatal diagnosis and choose to continue the pregnancy, the place and time of delivery can be tailored to the intended surgical management.

Babies with hypoplastic left heart syndrome have tachypnea and mild cyanosis. There is a moderate right ventricular impulse, a single second heart sound, and a third heart sound. Murmurs, if present, are caused by increased pulmonary flow or tricuspid valve regurgitation. If the ductus arteriosus is patent, the pulses can be nearly normal; however, as the ductus arteriosus closes, it is difficult to palpate the pulses, and the perfusion is poor.

A restrictive atrial septal defect is initially beneficial because it tends to limit the pulmonary blood flow and promote systemic blood flow. However, if the atrial septal defect is highly restrictive, total pulmonary resistance is very high, and pulmonary blood flow is markedly diminished. Left atrial and pulmonary venous pressures are high, and pulmonary edema is present. The combination of pulmonary edema and restricted pulmonary blood flow produces profound hypoxia.[10,35]

LABORATORY EVALUATION

The electrocardiogram shows dominant right ventricular forces, often with a QR pattern in the right chest leads. Pulse oximetry averages 70% to 90%, depending on the pulmonary blood flow and the degree of pulmonary edema. The chest radiograph shows cardiomegaly and increased pulmonary blood flow with some degree of pulmonary venous congestion. The echocardiogram (Fig. 45-18) defines right ventricular function, tricuspid regurgitation, venous anatomy, and the atrial septal defect, all possible risk factors for surgery.

MANAGEMENT AND PROGNOSIS

The ability to sustain the life of a baby with hypoplastic left heart syndrome by maintaining ductal patency and systemic blood flow with prostaglandin E_1 and the advances in neonatal cardiopulmonary care have made both the Norwood operation and cardiac transplantation (see also Part 10) important therapies for these neonates. The choice of the Norwood operation or cardiac transplantation[13] is guided by several factors, including donor availability and the evolving experience and results with both approaches. The improved

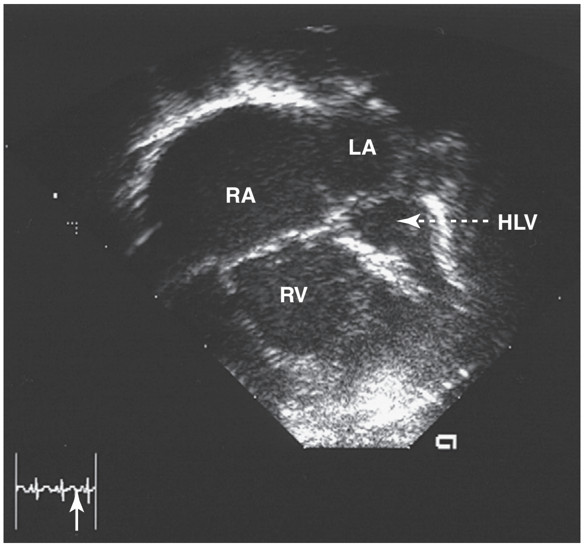

Figure 45–18. Neonate with diminished pulses and poor perfusion. Echocardiogram showed left-sided hypoplasia with a 3-mm aortic valve and a 4-mm mitral valve. Apical four-chamber view demonstrates marked size discrepancy between right ventricle (RV) and hypoplastic left ventricle (HLV). RA, right atrium; LA, left atrium.

results of the staged Norwood palliation since the mid-1990s have favored this approach over transplantation in many centers, except in babies with poor ventricular function.[48] Careful preoperative assessment and management for preventing the complications of excessive pulmonary blood flow are essential for good long-term results.

The goal of the Norwood stepwise approach to the surgical management of hypoplastic left heart syndrome is first to ensure systemic blood flow and protect the lungs from excessive pulmonary flow and pulmonary hypertension. Subsequently, the systemic venous drainage and the pulmonary venous drainage are separated, providing normal arterial oxygen saturation and ventricular stroke volume. The surgical management has evolved during the past decade in the effort to solve problems recognized during the early experience with the operation.

The first-stage operation, done in the newborn period with the use of cardiopulmonary bypass, fundamentally changes the defect from aortic atresia to pulmonary atresia. The branch pulmonary arteries are separated from the main pulmonary artery. The ascending aorta is opened along its length from at least the transverse aorta to distal to the ductus arteriosus. The main pulmonary artery is anastomosed to the aorta, and the anastomosis is augmented, when necessary, with homograft tissue to minimize the distortion of the arch and relieve any area of coarctation. The pulmonary blood flow is established by a shunt between the systemic and the pulmonary circulation. An alternative to the aortic-to-pulmonary shunt is a right ventricle-to-pulmonary shunt (*Sano modification*).[19] The atrial septum is excised to prevent any pulmonary venous obstruction.

A second alternative strategy has developed with the advent of a hybrid, interventional catheterization and surgery, approach to hypoplastic left heart syndrome. The first-stage palliation is replaced with stenting of the patent ductus arteriosus and banding of the branch pulmonary arteries. The actual arch reconstruction is done at a second stage at the time of a bidirectional Glenn procedure.[32] The potential advantage of this approach is that it can avoid circulatory arrest in the newborn and shifts the major surgical procedure to an older age.

The postoperative management of the infant after the first stage of the Norwood operation follows principles similar to those for the preoperative care; however, the restriction of pulmonary blood flow by the systemic-to-pulmonary or right ventricle-to-pulmonary shunt permits a greater flexibility in modulating the systemic vascular resistance with afterload reduction and increased carbon dioxide. This, coupled with inotropic support, has improved systemic oxygen delivery without excessive pulmonary blood flow. Even in the era of improved surgical and intensive care techniques, a proportion of newborns after first-stage palliation require extracorporeal membrane oxygenation support for 24 to 48 hours to achieve stability.[84]

The second stage of the Norwood operation exchanges the shunt between the systemic and the pulmonary circulation for a bidirectional Glenn anastomosis or a hemi-Fontan operation.[28] This operation, done between 2 and 6 months of age, directs the superior vena caval blood flow to both right and left pulmonary arteries. The previous shunt is ligated, and the systemic venous return from the upper half of the body becomes the sole source of pulmonary flow. The typical result is an arterial saturation of 70% to 75%. The volume load on the ventricle is reduced, and the possibility of ventricular systolic or diastolic dysfunction is minimized.

The final surgical step, done between 12 months and 3 years of age, is to completely separate the systemic and the pulmonary venous return by a modification of the Fontan operation. The superior aspect of the right atrium is anastomosed to the underside of the pulmonary artery, and the atrium is partitioned with a baffle to direct the inferior vena caval flow into the pulmonary artery. Alternatively, an extracardiac conduit can be placed between the inferior vena cava and the right pulmonary artery. Although this technique is usually used in older children, it offers the advantage that it can be done without cardiopulmonary bypass and requires fewer suture lines in the atrium.[80] Limiting the atrial suture lines can reduce the long-term risk for arrhythmias.

The cumulative mortality and morbidity rates during the development of the Norwood operation were high. The early experience with first-stage palliation resulted in a 1-year survival rate of less than 50%. The most recent experience has improved these first-stage results, and the staged approach through the Glenn to the Fontan operation shows considerable early promise for improved quality of life and survival.[7,26,48] Most series comparing the traditional systemic-to-pulmonary shunt with the Sano modification or the hybrid have failed to demonstrate a significant difference in outcome.[30,34,45] A multicenter prospective clinical trial is underway comparing Blalock-Taussig and right ventricle-to-pulmonary artery shunts in the Norwood procedure.[76]

Risk factors for poor first-stage survival are low birthweight, a highly restrictive atrial septal defect, ventricular dysfunction, and tricuspid regurgitation.[10,26,48,91,105] Long-term morbidity includes recurrent coarctation,[60] AV valve regurgitation, sinus node dysfunction, and ventricular dysfunction. The improved mortality rate provides an opportunity to assess the impact of multiple surgeries and underlying central nervous system defects on neurodevelopmental outcome. Early data suggest that babies with hypoplastic left heart syndrome are at a higher risk for neurodevelopmental delay.[8,37,54,66]

Multiple Left Heart Defects

Associated left heart defects are common and can be multiple. Mitral valve abnormalities can be subtle, with mild hypoplasia and minimal distortion of the chordal and papillary muscle geometry. Shortening and fusion of the chordae tendineae or alterations in papillary muscle spacing increase the obstruction of the mitral valve. A single mitral valve papillary muscle (parachute deformity) causes significant stenosis.[47,93,103] Mild subaortic obstruction is seen with an isolated thin membrane just below the aortic valve. As the narrowing becomes more diffuse, it tends to be more severe and is associated with more severe forms of aortic valve disease. Coarctation of the aorta with varying degrees of aortic arch hypoplasia is an important component of multiple defects of the left side of the heart. The consequence of abnormal left ventricular inflow, because of either mitral valve disease or abnormal left ventricular diastolic function, is the additional component of left ventricular hypoplasia.

Atrial septal defects in neonates with left heart defects usually consist of stretching and incompetence of the foramen ovale as a result of left atrial hypertension rather than true defects of tissue. Associated ventricular septal defects can significantly alter the presentation and pathophysiology of neonates with left heart defects. Even a ventricle of small to moderate size can allow significant left-to-right shunting in a neonate with aortic stenosis or coarctation of the aorta. If there is mitral stenosis or left ventricular hypoplasia, filling of the aorta will occur through the ventricular septal defect. If the defect is large, the aortic valve and arch can be normal, and systemic blood flow will be preserved. A smaller defect might be inadequate to support systemic flow at birth or in the first weeks of life.

ACYANOTIC DEFECTS WITH NO OR MILD RESPIRATORY DISTRESS

Normal Murmurs

Normal murmurs are generated by laminar blood flow across normal valves into normal blood vessels. The vibratory systolic ejection murmur heard in newborn infants radiates uniformly over the chest. The vibratory systolic ejection murmurs from the pulmonary artery that are localized to the upper left sternal border and are heard from the aorta from the lower left sternal boarder radiating to the neck, which are heard in older children, are unusual in neonates. The precordial activity, second heart sound, and pulses are normal.

The murmur is best heard with the baby breathing quietly and is obliterated by crying or straining. Clearly pulmonary in origin by its radiation to the lungs, it is similar to but less harsh than the murmur heard in babies with branch pulmonary artery stenosis. Thus, despite the absence of true stenosis, it has been labeled *peripheral pulmonary artery stenosis*. Perhaps the addition of the word *physiologic* would help clarify its normalcy.

Echocardiographic studies suggest that this murmur arises from the abrupt increase in velocity as the flow in the main pulmonary arteries turns into relatively small branch pulmonary arteries.[90] This size difference is due to the fetal circulation, which largely bypasses the lungs across the ductus arteriosus. An increase in velocity from 1.4 to 2.5 m per second is typical as the 8-mm main pulmonary artery branches into 3-mm left and right pulmonary arteries.

The murmur of physiologic peripheral pulmonary artery stenosis is accentuated by increased pulmonary flow caused by an atrial septal defect or a patent foramen ovale. If the murmur has harsh components and is best heard at the upper left sternal border, mild pulmonary stenosis should be considered. With growth during the first year, the size discrepancy between the main and the branch pulmonary arteries resolves, and the acceleration of flow into the lungs is considerably lower. Laboratory studies are rarely needed to diagnose this condition and are needed only if the murmur persists beyond infancy.

Pulmonary Stenosis

ANATOMY AND PATHOPHYSIOLOGY

Neonatal valvular pulmonary stenosis is differentiated from critical pulmonary stenosis or atresia by the presence of a normal tricuspid valve and normal right ventricular size. The pulmonary annulus is normal, and the valve leaflets are thickened and fused. Poststenotic dilation of the main and proximal branch pulmonary arteries is present. A thickened, immobile, dysplastic valve might not have any enlargement of the pulmonary arteries. Right ventricular systolic and diastolic function is normal, and atrial-level right-to-left shunting is unusual. Right ventricular pressure and hypertrophy are in proportion to the degree of obstruction. Right ventricular pressure is less than left ventricular pressure.

ASSOCIATED DEFECTS

Babies with severe stenosis usually have a component of dynamic subpulmonary stenosis. Branch pulmonary artery stenosis is atypical in association with valvular pulmonary stenosis. Atrial-level left-to-right shunting is common, and the increased flow across the pulmonary valve can exaggerate the estimate of severity by pressure gradient.

CLINICAL PRESENTATION

Neonates with pulmonary stenosis are free of symptoms and are identified by auscultation of an early systolic ejection click or a harsh systolic ejection murmur that radiates to the lungs. The intensity of the murmur correlates with the severity of obstruction. In moderate or severe stenosis, the right ventricular impulse persists, and the pulmonary component of the second heart sound is diminished and delayed. The peripheral pulses and liver are normal.

LABORATORY EVALUATION

Examination of all neonates with the clinical diagnosis of pulmonary stenosis is warranted. The differentiation from tetralogy of Fallot on clinical examination alone can be unreliable.

The electrocardiogram of neonates with pulmonary stenosis is normal. The chest radiograph might show dilation of the pulmonary artery segment, although it is often obscured by the thymus. Echocardiography is diagnostic, especially with moderate or severe stenosis. Because the entire cardiac output crosses the valve, the gradient estimated by Doppler study is an accurate measure of severity. The normal neonatal pulmonary valve is somewhat echogenic, and occasionally newborn infants who have very mild pulmonary valve stenosis on newborn echocardiograms are found to be normal on later follow-up.

MANAGEMENT AND PROGNOSIS

The natural history of isolated valvular pulmonary stenosis is excellent. Neonates with moderate or severe stenosis should be followed closely because progression during the first few months of life does occur. Pulmonary balloon valvuloplasty (see "Neonatal Interventional Catheterization" in Part 10) is indicated for infants with severe stenosis. Despite significant pressure loading of the right ventricle, these infants rarely have symptoms, and the timing of the procedure is determined by the gradient and the severity of right ventricular hypertrophy. Balloon valvuloplasty for children with moderate stenosis is undertaken between 1 and 3 years of age. Surgical pulmonary valvotomy is now reserved for infants with dysplastic pulmonary valves who do not respond to balloon valvuloplasty or for children with associated atrial septal defects.

Ventricular Septal Defect

ANATOMY AND PATHOPHYSIOLOGY

Defects in the ventricular septum occur in the inlet septum, muscular septum, perimembranous septum, and supracristal portion of the septum. The defects could be any size from less than 1 mm to the size of the aorta and can occur in combination. High pulmonary vascular resistance at the time of birth effectively limits shunt through the defect. With the fall in the pulmonary vascular resistance during the first few days of life, flow increases across the defect. Primarily, this flow is throughout systole from the left ventricle to the right ventricle, although diastolic flow can occur. The extent of flow across the defect is determined by the size of the defect and the relative systemic and pulmonary vascular resistance. Small defects, even with low pulmonary vascular resistance, do not allow significant shunting. Large defects allow equalization of pressures in the right and left ventricles, and the flow across the defect is limited only by the relative systemic and pulmonary vascular resistance.

ASSOCIATED DEFECTS

Ventricular septal defects are commonly seen in association with many other cardiovascular defects. Left-heart defects, especially aortic stenosis and coarctation of the aorta, can dramatically change the natural history of either defect in isolation.

CLINICAL PRESENTATION

Small perimembranous ventricular septal defects are routinely identified by their characteristic holosystolic murmur at the time of the discharge physical examination. Similarly, small muscular ventricular septal defects have a harsh early systolic murmur. The abbreviated nature of the murmur is likely due to a change in the size of the defect during systole. Even at 1 or 2 days of age, the pulmonary vascular resistance has fallen enough to establish turbulent flow across the defect. The babies have no symptoms, and the remainder of the examination findings are normal, including the precordial activity, second heart sound, and pulses.

Larger defects can be more challenging to identify before discharge because the large defect offers no resistance to flow and generates no turbulence, despite the early changes in the pulmonary vascular resistance. A persistent right ventricular impulse or narrow splitting of the second heart sound, or a low-frequency systolic murmur, can be a clue to the underlying defect. However, most children with isolated ventricular septal defect are discharged from the hospital with no symptoms, and many ventricular septal defects are not diagnosed until the first well-child check at several weeks of age.

LABORATORY EVALUATION

Small ventricular septal defects are easily diagnosed on a clinical examination. The electrocardiogram and chest radiograph are normal and, although reassuring, are not diagnostic. Echocardiographic diagnosis of ventricular septal defects by imaging and color flow mapping is accurate and provides reassurance that associated defects are not present. If the typical murmur persists or if there is any question about the diagnosis, echocardiography is indicated. If a large defect is suspected on clinical examination, even in the symptom-free baby who is ready for discharge, an echocardiogram is essential to exclude more complex disease.

MANAGEMENT AND PROGNOSIS

Spontaneous closure of small and some large ventricular septal defects is common. Small defects do not cause symptoms even when they stay patent. Larger defects can cause congestive heart failure in the first months of life and present a long-term risk for pulmonary vascular disease. If there is no evidence of spontaneous closure except a finding of persistent congestive heart failure or pulmonary hypertension, surgical repair is indicated in infancy.

Atrial Septal Defect

An isolated ostium secundum atrial septal defect in a neonate is nearly always an incidental finding on an echocardiogram obtained to evaluate a murmur. Many apparent defects in neonates represent stretching or incomplete closure of the foramen ovale and resolve by 1 year of age. This is especially true of babies with associated patent ductus arteriosus or ventricular septal defect in whom increased left atrial pressure stretches the atrial septum and permits shunting across the foramen ovale. Clinical signs of an atrial septal defect on routine follow-up during childhood indicate the need for further cardiovascular evaluation at that time.

Endocardial Cushion Defects

ANATOMY AND PATHOPHYSIOLOGY

Endocardial cushion defects are a spectrum of malformations resulting from failure of the endocardial cushions to fuse completely. The most severe malformation is a complete AV septal defect with a common AV valve, a large inlet ventricular septal defect, and a large ostium primum atrial septal defect. Intermediate forms have a small ventricular component, together with some separation of the tricuspid and mitral components of the AV valves. Ostium primum atrial septal defect and cleft mitral valve are milder forms of endocardial cushion defects.

The pathophysiology of endocardial cushion defects is similar to that of perimembranous ventricular septal defect and ostium secundum atrial septal defects. A high degree of pulmonary vascular resistance in the newborn period effectively limits the flow across the defects, and neonatal problems are unusual.

ASSOCIATED DEFECTS

A small degree of AV valve regurgitation is common; however, significant regurgitation causes early congestive heart failure. Common atrium is a form of endocardial cushion defect and is associated with anomalies of the systemic and pulmonary veins, including left superior vena cava to the roof of the left atrium. Unbalanced ventricular development with right or left ventricular hypoplasia can be associated with hypoplasia of the mitral or tricuspid component or with obstruction of the aortic or pulmonary outflow.

CLINICAL PRESENTATION

Endocardial cushion defects are common in babies with Down syndrome, and a large number of these defects are diagnosed as part of the evaluation for Down syndrome in the nursery (see Chapter 29). The high-pitched holosystolic murmur of mitral regurgitation can be heard in the nursery. However, the septal defects present the same limitations that preclude routine neonatal diagnosis of ostium secundum atrial septal defects and ventricular septal defects. Cyanosis caused by atrial right-to-left shunting is present in some neonates with large AV septal defects, especially if there is tricuspid regurgitation.

LABORATORY EVALUATION

The electrocardiogram of babies with endocardial cushion defects is helpful because the maldevelopment of the endocardial cushion produces abnormal activation of the left anterior bundle. These babies have an abnormal superior frontal plane vector (left axis deviation). They are easily differentiated from the baby with tricuspid atresia because they have normal right ventricular forces.

MANAGEMENT AND PROGNOSIS

Elective repair of complete AV septal defects is done in the first several months of life with a high degree of success.[99,100] Long-term issues are primarily AV valve function. Infants with less extensive defects, no pulmonary hypertension, or failure to thrive undergo repair in the first year of life.

Patent Ductus Arteriosus

ANATOMY AND PATHOPHYSIOLOGY

The ductus arteriosus, connecting the pulmonary artery and the aorta, is an essential structure during fetal life. Because fetal pulmonary vascular resistance is high, nearly 90% of the blood ejected by the fetal right ventricle flows through the ductus arteriosus to the descending aorta. The ductus arteriosus closes in the first few days after birth, and the entire right ventricular output is ejected into the pulmonary arterial bed.

If the ductus arteriosus remains patent postnatally and pulmonary vascular resistance falls, blood flow through the ductus arteriosus is from the aorta to the pulmonary artery. Furthermore, because the connection is open during both systole and diastole and pulmonary artery pressure is lower than the respective aortic pressure, blood flows across the patent ductus arteriosus continuously throughout the cardiac cycle. The volume overload and enlargement of the pulmonary artery, pulmonary veins, left atrium, left ventricle, and aorta are directly related to the volume of blood through the patent ductus arteriosus, which in turn is determined by the size of the ductus arteriosus and the relative systemic and pulmonary vascular resistances.

An important exception to this pattern of left atrial and left ventricular volume loading occurs in newborn infants with persistent transitional circulation. In these infants, the pulmonary vascular resistance is comparable to or higher than the systemic vascular resistance. Blood flow during systole is from the pulmonary artery to the aorta and from the aorta to the pulmonary artery in diastole. If the pulmonary vascular resistance is significantly higher than systemic resistance, flow across the ductus arteriosus is from pulmonary artery to aorta in both systole and diastole.

The mechanisms responsible for constriction of the ductus arteriosus at birth are not fully understood. The ductus arteriosus is highly sensitive to changes in oxygen tension; the increase in arterial oxygen tension that normally occurs after birth probably serves as the stimulus for closure of the ductus arteriosus. How this response is mediated is less certain; it is likely attributable to a complex interaction between autonomic chemical mediators, nerves, prostaglandin, and the ductal musculature. The ductus arteriosus functionally closes in most full-term infants during the first day of life, but anatomic obliteration of the ductus arteriosus does not occur until after the first week of life. A persistently patent ductus arteriosus is uncommon in otherwise normal children. In contrast, 30% of infants who weighed less than 1.5 kg at birth have a patent ductus arteriosus, possibly as a result of hypoxia and immaturity of the ductal closure mechanisms.[87] Spontaneous permanent PDA closure only occurred by 4 postnatal days in approximately one third of infants <1000 g birth weight.[56a] Therefore, a majority of such infants are potential candidates for pharmacologic or surgical intervention, although the merits of active therapy for PDA closure are controversial.

ASSOCIATED DEFECTS

A patent ductus arteriosus is present at birth in all but a few congenital heart defects. Although the presenting features of the associated defects are usually clear, occasionally the ductus arteriosus is the most easily recognized component clinically and by echocardiogram. Coarctation of the aorta is clearly more difficult to diagnose in the presence of a large ductus arteriosus.

The absence of the ductus arteriosus is notable in some neonates with tetralogy of Fallot and pulmonary atresia. In these babies, the central pulmonary arteries are markedly hypoplastic where the ductus would insert, and there are aortic-to-pulmonary collateral vessels from other sites. The ductus arteriosus is also often absent in neonates with the absent pulmonary valve syndrome, in which the failure of ductal formation or closure at a critical time in cardiogenesis can play a role in the pathogenesis of the pulmonary valve and arterial abnormality.

CLINICAL PRESENTATION

The clinical presentation of the neonate with a patent ductus arteriosus is unlike that of the infant or child in whom a continuous murmur is the classic feature. In newborn infants, especially premature ones, the diastolic flow through the ductus arteriosus is difficult to hear. A systolic murmur with uneven intensity throughout systole is best heard at the upper left sternal border. Even in the absence of a murmur, the hemodynamic consequences of a patent ductus arteriosus could be clinically evident. Increased pulmonary blood flow causes an oxygen requirement and difficulty in weaning the infant from ventilatory support. The left ventricular volume load produces an increased left ventricular impulse or a third heart sound. The diastolic flow into the pulmonary artery lowers aortic diastolic pressures, causing bounding pulses. These clinical signs can lag behind echocardiographic signs of a significant patent ductus arteriosus.[97]

LABORATORY EVALUATION

In babies with symptoms, the clinical suspicion of a patent ductus arteriosus should be confirmed by echocardiography. Similar physical findings are present in infants with aortic-pulmonary collateral vessels, an aortic-pulmonary window, origin of the right pulmonary artery from the ascending aorta (hemitruncus), fistula between the coronary artery and the right ventricle, and a ruptured sinus-of-Valsalva aneurysm. Echocardiography (Fig. 45-19) permits an accurate diagnosis—with assessment of both the hemodynamic impact of the shunt, as reflected by the extent of left atrial and ventricular enlargement, and the estimated pulmonary artery pressure by Doppler imaging—and excludes other associated defects. Electrocardiography is of limited value in the assessment. Chest radiographs offer an estimate of heart size but are not diagnostic. B-type natriuretic peptide (BNP) is produced in response to increased myocyte stretch and may be a useful bedside screening tool for the presence of a PDA or response to therapy in premature infants.[38a, 46a]

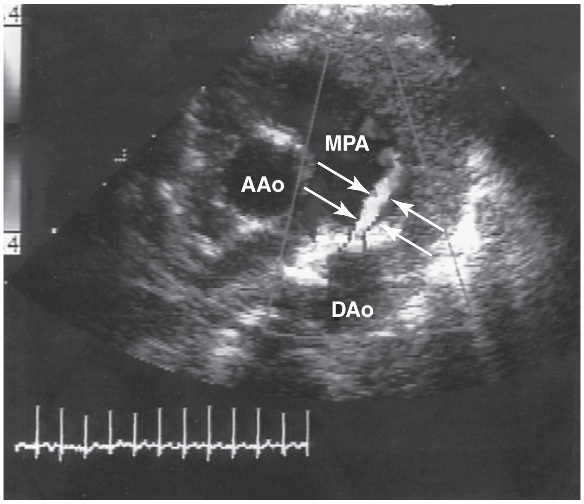

Figure 45–19. Color flow Doppler study showing small patent ductus arteriosus with flow outlined by *arrows* from descending aorta (DAo) to main pulmonary artery (MPA) in parasternal short-axis view. AAo, ascending aorta.

MANAGEMENT AND PROGNOSIS

Full-term neonates with the clinical diagnosis of a small patent ductus arteriosus can be followed clinically. Careful assessment of the precordial activity and pulses and documentation of normal pulse oximetry usually is adequate to exclude clinically important associated heart defects in a symptom-free baby. An electrocardiogram and a chest radiograph can be reassuring but are of limited value beyond the clinical examination. If there is uncertainty about the diagnosis or if symptoms develop, the diagnosis should be confirmed by echocardiography.

Spontaneous closure of a patent ductus arteriosus can occur in the first months of life. Persistent ductal patency does have an important long-term risk for bacterial endocarditis, and closure is usually recommended after age 6 months. Conventional surgical closure or video-assisted thoracoscopic surgery[20] is appropriate for infants with a moderate to large patent ductus arteriosus. Interventional catheterization closure with coils is useful for smaller defects (see “Neonatal Interventional Catheterization” in Part 10).

In the premature infant, spontaneous closure is common; however, persistent or recurrent congestive heart failure and respiratory distress can require therapy to close the ductus arteriosus. A rapid or progressive increase in ventilator settings and inspired oxygen can be manifestations of congestive heart failure caused by a patent ductus arteriosus in such patients. Medical management with fluid restriction and diuretics is occasionally effective.

Indomethacin, a prostaglandin synthetase inhibitor, has been shown to close the ductus arteriosus in a large fraction of premature infants up to 14 days of age and occasionally as late as 1 month of age. A common dosing regimen is 0.1 to 0.2 mg/kg per dose given intravenously, administered at 12- to 24-hour intervals for up to three doses. Contraindications to indomethacin therapy are renal failure (creatinine concentration level higher than 1.2 to 1.5 mg/dL), active bleeding, or significant thrombocytopenia. Failure of indomethacin therapy has been related to extreme immaturity and to greater postnatal age at initiation of therapy.[106] Longer treatment courses can be used (0.1 to 0.2 mg/kg per day) for 5 days. However, there appears to be no clear advantage to prolonged low-dose indomethacin regimes for patent ductus arteriosus closure[100] (see Appendix A).

Prophylactic indomethacin improves the rate of permanent ductus closure by increasing the degree of initial constriction. Narayanan and associates[73] showed that prophylactic indomethacin neither affected the remodeling process nor altered the inverse relationship between infant maturity and subsequent reopening. Even when managed with prophylactic indomethacin, the rate of ductus arteriosus reopening remained unacceptably high in the most immature infants. Prophylactic indomethacin has its advocates, and an additional benefit of this approach could be to decrease the incidence of intraventricular hemorrhage (see Chapter 40, Part 3). However, a large prospective study that documented a decrease in the incidence of patent ductus arteriosus from 50% to 25% failed to alter the incidence of intraventricular or periventricular hemorrhage or to improve neurodevelopmental outcome at 18 months of corrected age.[94] Using echocardiography to direct the duration of indomethacin therapy appears to achieve similar closure rates while limiting drug exposure and its attendant risks.[20a]

Ibuprofen has been shown to be equally effective for ductal closure with fewer renal side effects.[81] Surgical ligation of the ductus arteriosus has been associated with increased morbidity and adverse neurodevelopmental outcome.[65] A relatively high incidence of left vocal cord paralysis has been reported postoperatively in extremely low birth weight infants.[15a] Surgery is indicated if the ductus arteriosus remains hemodynamically significant by clinical or echocardiographic criteria after indomethacin or ibuprofen therapy, or if pharmacotherapy is contraindicated.

Aortopulmonary Window

ANATOMY AND PATHOPHYSIOLOGY

An aortopulmonary window is typically a large defect between the ascending aorta and the main pulmonary artery. Smaller, restrictive defects do occur but are the exception. The pathophysiology mimics a patent ductus arteriosus with pulmonary hypertension and a left-to-right shunt that increases as the pulmonary vascular resistance falls.

ASSOCIATED DEFECTS

An aortopulmonary window can be seen in conjunction with aortic arch interruption or tetralogy of Fallot.

CLINICAL PRESENTATION

Clinical signs of congestive heart failure can occur in the first week of life. Precordial hyperactivity, a single second heart sound, a low-frequency systolic murmur of increased pulmonary blood flow, and bounding pulses might be evident even before tachypnea and poor feeding become problems.

LABORATORY EVALUATION

The electrocardiogram is normal in the neonatal period and shows combined ventricular hypertrophy as the pulmonary vascular resistance falls and pulmonary blood flow increases. The chest radiograph demonstrates cardiomegaly and increased pulmonary vascular markings. Echocardiography shows the defect; however, specific attention must be directed to excluding an associated patent ductus arteriosus or aortic arch interruption.

MANAGEMENT AND PROGNOSIS

Surgical closure of an aortopulmonary window is usually done shortly after diagnosis, with excellent short- and long-term results.[12]

L-Transposition of the Great Arteries

ANATOMY AND PATHOPHYSIOLOGY

L-Transposition of the great arteries, or ventricular inversion, is the connection of the right atrium to the left ventricle and of the left ventricle to the pulmonary artery, and the connection of the left atrium to the right ventricle and of the right ventricle to the aorta. The ventricles are usually side by side, with the ventricular septum directed from the anterior to the posterior portion. The anatomic right ventricle is to the left, and the anatomic left ventricle is to the right. The aorta is anterior and to the left, and the pulmonary artery is posterior and to the right. Because the aorta arises from the right ventricle, a subaortic infundibulum is present, and the aortic valve is superior to the pulmonary valve.

Unless associated lesions are present, there is no shunting, but normal pressures and saturations are found in the aorta and pulmonary artery. Because the systemic ventricle is the anatomic right ventricle in this condition, right ventricular systolic pressure is comparable to aortic pressure. Similarly, the pulmonary ventricle is the anatomic left ventricle and has low systolic pressure.

ASSOCIATED DEFECTS

Associated defects are nearly always found in babies with L-transposition of the great arteries. Ventricular septal defect, pulmonary stenosis, and Ebstein malformation of the tricuspid valve are frequent. L-Transposition of the great arteries with hypoplastic subaortic left ventricle, restrictive ventricular septal defect, and coarctation of the aorta is a well-recognized form of single ventricle. Acquired complete AV block occurs in children with L-transposition of the great arteries and might be present at birth.

CLINICAL PRESENTATION

Uncomplicated L-transposition of the great arteries is rare and is unlikely to be detected in the newborn period. Associated defects are diagnosed because of cyanosis or murmurs.

LABORATORY EVALUATION

The electrocardiogram might be abnormal in the newborn period because of abnormal septal activation with Q waves in the right chest leads. On the chest radiograph, the ascending aorta forms a straight left heart border that angles medially to the superior mediastinum. A methodical echocardiogram is necessary for identifying the spatial and anatomic connections.

MANAGEMENT AND PROGNOSIS

Management and prognosis are driven by the associated lesions. The prognosis in uncomplicated L-transposition of the great arteries can be excellent with good long-term systemic right ventricular function. Severe Ebstein malformation of the tricuspid valve is a cause of severe neonatal congestive heart failure. Repair or replacement of the systemic AV valve has limitations.[104] For infants and children with systemic right ventricular failure, a combined atrial and arterial switch operation might offer improved survival.[29]

PART 8

Cardiovascular Problems of the Neonate

Kenneth G. Zahka

CARDIAC MALPOSITION AND ABNORMALITIES OF ABDOMINAL SITUS

The normal cardiac position is the ventricular apex pointed to the left with the left atrium and stomach on the left and the right atrium and liver on the right. The morphologic three-lobed lung is on the right, and there is early branching of the right bronchus with an epiarterial bronchus. The morphologic two-lobed lung is on the left, with a long segment of left main bronchus before the bronchus branches.[31] The assessment of normal cardiac position can be made by physical examination and by routine chest radiography and echocardiography. Abdominal situs is ascertained by palpation of the liver; an abdominal radiograph for the stomach bubble; and ultrasonography to define the stomach, liver, and spleen. A liver-spleen scan might be helpful in finding the spleen if it is not seen on ultrasonography. Howell-Jolly bodies are seen on a blood smear in patients who do not have normal splenic function.

Dextrocardia is present when the heart is in the right side of the chest. If the heart is in the midline, mesocardia is present. Situs solitus is the normal location of the atria and abdominal organs. Situs inversus is present when the right atrium is on the left, the left atrium is on the right, and the liver and stomach are similarly reversed. In situs inversus, the morphologic right lung is on the left, and the morphologic left lung is on the right. Situs ambiguous, with the liver and stomach in the midline, is seen in neonates with bilateral right-sidedness or bilateral left-sidedness. Babies with bilateral right-sidedness have asplenia, and their atrial and pulmonary morphologic features are characteristic of bilateral right atria and lungs. Babies with bilateral left-sidedness have polysplenia and bilateral morphologic left atria and lungs.

Associated Lesions

The importance of these cardiac and situs abnormalities lies in the associated lesions. Dextrocardia with situs inversus is a mirror image of normal anatomy and often has no associated cardiac lesions. It could, however, be associated with Kartagener, or immotile cilia, syndrome. In contrast, babies with dextrocardia with situs solitus often have associated congenital heart defects, including uncomplicated septal defects and L-transposition of the great arteries. Neonates with situs inversus with levocardia always have associated heart defects. Intestinal obstruction can cause intestinal malrotation in these babies.[8]

Asplenia syndrome should be suspected whenever complex heart defects are associated with total anomalous pulmonary venous connection.[50] Because there is no morphologic left atrium, pulmonary venous drainage is rarely directly to the atrium. Similarly, the coronary sinus, which lies posterior to the normal left atrium, is usually absent. Systemic venous drainage is also abnormal, with bilateral superior venae cavae. The left superior vena cava might enter directly into the roof of the left-sided morphologic right atrium, whereas the right superior vena cava enters the right atrium in a normal fashion. The right inferior vena cava is present, and there might be an additional left inferior vena cava. Dextrocardia, with a common atrium and a single atrioventricular valve, and either a common ventricle or a large ventricular septal defect, is common. Severe pulmonary stenosis or atresia is common.[12] In addition to the liability of complex congenital heart disease, these babies are immunologically compromised because of their asplenia.[52] Daily administration of a prophylactic antibiotic to reduce the risk for bacterial sepsis is important.

Absent hepatic segment of the inferior vena cava, so-called interrupted inferior vena cava, is an excellent clue to the presence of polysplenia in a neonate with ambiguous abdominal situs.[60] Because there is no right atrium, the course of the inferior vena cava is not normal. Drainage of the inferior vena cava is to the azygos or hemiazygos veins and into the superior vena cava. With bilateral left atria, the pulmonary veins also usually enter in a bilateral fashion. Polysplenia is often associated with levocardia, normally related great arteries, a common atrium, and two ventricles with a ventricular septal defect. The pulmonary valve is usually normal. Although there are multiple small spleens, splenic function is typically normal, although the presence of Howell-Jolly bodies on blood smear may indicate hyposplenism in some patients.[45]

COR PULMONALE

See also Chapter 44, Part 7.

Cor pulmonale is heart disease caused by chronic lung disease or upper airway obstruction. It is the result of abnormal cardiovascular systolic and diastolic loading, at least in its early phases, related to increased right ventricular afterload caused by hypoxic pulmonary vasoconstriction. Other factors, including loss or underdevelopment of pulmonary parenchyma and its associated vascular bed, can also be important in infants with bronchopulmonary dysplasia[23] or diaphragmatic hernia. If the normal fall in pulmonary vascular resistance does not occur because of lung disease, right ventricular hypertrophy will persist. Right ventricular dilation and dysfunction are usually present in proportion to the severity of the underlying lung disease.

Diagnosis

Clinical recognition of cor pulmonale can be hampered by respiratory distress and lung sounds from the underlying respiratory disease. A right ventricular impulse and narrow splitting of the second heart sound with an accentuated pulmonary closure sound should be present in infants with cor pulmonale but can be difficult to recognize. Hepatomegaly resulting from right ventricular diastolic dysfunction could be assumed to be due to hyperinflation.

Electrocardiographic evidence of right ventricular hypertrophy is usually associated with significant cor pulmonale. Echocardiography has a greater role in the screening and follow-up of cor pulmonale, especially in at-risk babies with difficult cardiac examinations. Initial and longitudinal echocardiographic evaluation provides the opportunity to demonstrate the earliest indications of this complication and to determine the degree of correlation between echocardiographic signs of cor pulmonale and the clinical severity of pulmonary dysfunction. With recognition of the importance of ventricular interdependence, echocardiographic parameters of ventricular function should be applied not only to the right ventricle but also to the left ventricle. Because in some babies the degree of hypoxia and respiratory distress can vary during the course of the day or during a period of several weeks, the echocardiographic signs of cor pulmonale can reflect in an integrated fashion the status of lung function averaged across time.

Changes in right ventricular diastolic size and geometry and increased right ventricular wall thickness are the early indicators of chronic cor pulmonale. The severity of these abnormalities often, but not always, correlates with the degree of clinical chronic pulmonary dysfunction. Infants with exacerbations of their disease can demonstrate acute changes in right ventricular physiology, expressed by increased pulmonary and tricuspid regurgitation velocities and by acceleration time, without dramatic changes in their chronic right ventricular hypertrophy and chamber dilation. Right ventricular diastolic dysfunction assessed by retrograde flow in the hepatic veins during atrial systole and changes in early and late diastolic filling patterns can also be useful in assessing babies with cor pulmonale.

Serum B-type natriuretic peptide can be elevated in patients with pulmonary hypertension and evidence of congestive heart failure. Serial measurements may also complement clinical and echocardiographic assessment of the response to therapy.

Cardiac catheterization has not been needed as part of the assessment of cor pulmonale because two-dimensional and Doppler echocardiography are normally used. Cardiac catheterization is essential, however, if there is any question about structural heart disease, including pulmonary venous obstruction as a cause of pulmonary hypertension, or if there is any uncertainty about the elevation (per kg) of pulmonary vascular resistance before starting pulmonary vasodilator medications. Aortic-to-pulmonary collateral vessels develop in babies with chronic lung disease and can be recognized by color flow mapping.[2] If the collaterals appear large, coil embolization at the time of cardiac catheterization can be helpful.

Treatment

Treatment of the lung disease and airway obstruction and relief of hypoxia are the foundation of therapy for cor pulmonale. Diuretics have been used to decrease pulmonary interstitial edema and fluid retention caused by right ventricular dysfunction. The value of digoxin therapy in babies with cor pulmonale remains controversial, although with careful monitoring, the risk for digoxin use should be minimal.

Initial studies using calcium channel blockers to decrease pulmonary vascular resistance did not demonstrate benefit and raised concerns that perfusion of vascular beds that are poorly ventilated would exacerbate hypoxia.[7] Inhaled nitric oxide has become the standard treatment for persistent pulmonary hypertension of the newborn and may be used for rescue treatment for acute exacerbations of pulmonary hypertension associated with chronic lung disease. The introduction of oral phosphodiesterase type 5 inhibitors, including sildenafil, into the treatment of pulmonary hypertension in children and adults has opened their use for the treatment of cor pulmonale associated with pulmonary hypertension.[54]

Coil embolization of collateral vessels or of a small ductus arteriosus (see "Neonatal Interventional Catheterization" in Part 10) can be performed and decreases pulmonary blood flow and left ventricular volume loading. The improvement in pulmonary function is modest, and other collateral vessels can develop.

Surgical closure of a larger patent ductus arteriosus should be considered early in the course of the disease to decrease the risk for surgical morbidity, which is higher in the setting of severe lung disease. Surgical closure of a small foramen ovale is also not advisable because left-to-right shunting is mild, and right-to-left shunting usually indicates significant right ventricular diastolic dysfunction.

Prognosis

The long-term prognosis for a baby with cor pulmonale is usually determined by the lung disease. Babies receiving long-term ventilatory therapy or in respiratory failure with severe right ventricular dilation have significant morbidity and mortality rates. Mild to moderate right ventricular dilation is often reversible as the lung disease improves and is not a factor in long-term quality of life. Significant pulmonary hypertension in the setting of chronic lung disease remains an important marker for mortality.[32]

ARTERIOVENOUS MALFORMATIONS

Diagnosis

Cerebral arteriovenous malformations manifest in the neonatal period with signs of congestive heart failure, including a hyperdynamic precordium and hepatomegaly. Most defects identified in the neonatal period are vein of Galen malformations, although neonates with large pial malformations and congestive heart failure have been described. Intracranial hemorrhage could be an additional presenting feature in the neonate with a pial arteriovenous malformation. A cranial bruit and a systolic ejection murmur of increased aortic and pulmonary artery flow are present. The chest radiograph shows cardiomegaly, and the echocardiogram demonstrates enlargement of all chambers and the ascending aorta and carotid arteries. Doppler study of the aorta usually indicates significant diastolic runoff in the carotid arteries. Color flow mapping is particularly useful in identifying the multiple flow channels into the vein of Galen.

Treatment

Medical therapy with inotropes and diuretics in neonates with congestive heart failure caused by cerebral arteriovenous malformations improves symptoms before surgical intervention. The use of digoxin is controversial in this group of neonates because of concern about poor renal perfusion and toxicity.[21] Surgical management of cerebral arteriovenous malformations is difficult because of their size and location and because of the multiple feeder vessels. Embolization, with catheter-delivered metal coils or cyanoacrylate, of the arterial and venous channels before surgery has improved the results; however, complete cure of the defect is still unusual. Mortality and morbidity rates have improved dramatically in the past decade, but neurologic function after a combined interventional and surgical approach can be abnormal in up to 50% of survivors.[35]

HYPERTENSION

See also Chapter 51.

Measurement of blood pressure in newborn and intensive care nurseries has become routine since the introduction of oscillometric methods (see Chapter 31). The principles of accurate blood pressure measurement that have been developed for children and adults apply to neonates. Proper cuff size is essential, and the variety of disposable cuffs available in nurseries should permit the use of a cuff that fits the upper arm or thigh with the bladder nearly encircling the extremity. When the neonate rests quietly, the correlation with arterial blood pressure has been good even in small premature babies, and normal values for systolic and diastolic blood pressures are well established (see Appendix B).

Healthy neonates might have blood pressure measured once during their hospital course, although the standard of care is not well defined. Babies in intensive care units have multiple measurements, and those with arterial catheters have continuous monitoring of blood pressure.

Diagnosis

In addition to routine blood pressure screening, nonspecific clinical clues or maternal factors, including neonatal irritability and lethargy, should prompt additional measurements. Guidelines established by the Second Task Force on Blood Pressure Control in Children indicate that for full-term babies in the first week of life, significant hypertension is a systolic blood pressure greater than 96 mm Hg, and severe hypertension is greater than 106 mm Hg. In the first month, the guidelines are 104 mm Hg for significant and 110 mm Hg for severe hypertension. For newborn premature babies, the upper limits of normal blood pressure range from 58/38 mm Hg at 1 kg to 65/42 mm Hg at 2 kg (see Appendix B).

The mechanisms of blood pressure regulation in the neonate are similar to those in the child and adult; however, the fundamental disease processes that trigger those pathways are less diverse in the neonate. The differential diagnosis of neonatal hypertension[24,72] is summarized in Box 45-10. The aortic arch obstructions can be readily diagnosed by palpation of brachial and femoral pulses and measurement of arm and leg blood pressure. In contrast with the older child, significant hypertension is not a consistent feature of neonates with coarctation of the aorta. Marked elevation of the blood pressure in neonates with vascular catheters should always suggest renovascular complications and may lead to hypertensive cardiomyopathy.[49] Aortic mural thrombi or catheter-related emboli can occur at any point, including during unsuccessful attempts, in the course of umbilical arterial catheterization. Ultrasound and Doppler flow studies of the aortic arch, renal vessels, and renal parenchyma usually clarify these etiologic factors.

Moderate hypertension, especially if it develops gradually, is well tolerated, and there is compensatory left ventricular hypertrophy to match the increased afterload. In some neonates with acutely increased blood pressure caused by renovascular complications, left ventricular dysfunction and diminished cardiac output develop. Therapy is indicated if the infant is symptomatic or if the hypertension is sustained above a mean of 70 mm Hg (see Appendix B). Afterload reduction with intravenous administration of sodium nitroprusside is necessary until renal and cardiac function improves.

BOX 45–10 Differential Diagnosis of Neonatal Hypertension

AORTIC ARCH OBSTRUCTION
Coarctation of the aorta
Aortic arch interruption
Descending aorta thrombosis

RENAL AND RENOVASCULAR PROBLEMS
Renal artery thrombosis or embolus
Renal artery stenosis
Renal vein thrombosis (late)
Cystic renal disease
Obstructive uropathy

PHARMACOLOGIC ADVERSE EFFECTS
Catecholamines
Cocaine
Dexamethasone
Theophylline

OTHER CAUSES
Exogenous fluid administration
Environmental cold or noise stress
Seizures
Chronic lung disease

Treatment

If urine output is poor because of renal dysfunction, fluid restriction is necessary. Orally administered angiotensin-converting enzyme inhibitors such as captopril are excellent antihypertensive agents; however, they are contraindicated in the treatment of babies with coarctation of the aorta, unilateral renal artery disease, and hyperkalemia. They also must be used with care in babies with chronic hypertension because an abrupt drop in blood pressure, even when the pressure is not outside the normal range, can cause neurologic and renal side effects.[24]

Thrombectomy is rarely needed in babies with hypertension caused by catheter complications unless complete thrombosis of the aorta occurs. Gradual recovery with a good long-term prognosis is typical.[20]

PERSISTENT PULMONARY HYPERTENSION (PERSISTENT FETAL CIRCULATION)

See also part 2 of this chapter and Chapter 44, Part 8.

The normal transition to the extrauterine circulation is multifaceted; however, central to the process is a dramatic decrease in pulmonary vascular resistance. The mediators of neonatal pulmonary vasodilation include mechanical factors relating to stretching of the lung, oxygen factors, and vascular endothelial factors.

Endothelin type 1 is a potent vasoconstrictor produced by the fetal vascular endothelium. The effect of endothelin type 1 is mediated through receptors in the endothelium and vascular smooth muscle. Constriction of vascular smooth muscle is probably mediated by inhibition of nitric oxide production by vasoactive peptides such as endothelin type 1. Nitric oxide is recognized as a potent vasodilator that likely has an important role in the fall in neonatal pulmonary vascular resistance, although a host of other mediators have the potential to mediate pulmonary vascular resistance.[33]

Etiology

Delayed relaxation of the pulmonary vascular bed is a feature of many neonatal pulmonary problems, including lung hypoplasia (e.g., congenital diaphragmatic hernia), meconium aspiration syndrome, perinatal asphyxia, bacterial pneumonia, and sepsis. It can also occur in the absence of obvious triggering diseases, presumably because of abnormal muscularization of pulmonary arterioles or transient defects in endothelial function.

High pulmonary vascular resistance causes pulmonary and right ventricular hypertension. The neonatal right ventricle is well adapted to this increased afterload because of the high in utero right ventricular pressures and rarely has difficulty in meeting the challenge of generating high pressures. Intracardiac shunting at the ductus arteriosus and foramen ovale produce the hallmark of the disease, namely hypoxemia out of proportion to abnormalities on the chest radiograph.

Two factors promote right-to-left atrial shunting through the foramen ovale. The fetal right ventricle is less compliant than the left ventricle, and high postnatal right ventricular pressures can compound this diastolic dysfunction. Blood returning to the right atrium crosses the atrial septum at the foramen ovale if right ventricular diastolic pressure is elevated. Perinatal asphyxia could be associated with dysfunction of the tricuspid papillary muscle, which causes tricuspid regurgitation. The tricuspid regurgitation increases right atrial pressures and causes right-to-left shunting during ventricular systole. In some babies, color flow mapping can demonstrate a jet of tricuspid regurgitation directed into the fossa ovalis. Atrial-level right-to-left shunting causes left atrial, left ventricular, and systemic arterial desaturation. In this way, the disease mimics right heart defects such as critical pulmonary stenosis with impaired right ventricular filling.

Right-to-left ductal-level shunting in neonates with persistent pulmonary hypertension of the newborn (PPHN) occurs primarily during ventricular systole (Fig. 45-20). During diastole, there is left-to-right shunting. However, when the pulmonary vascular resistance is very high, shunting from the pulmonary artery to the aorta can occur during diastole. If right-to-left shunting is limited to the ductus, systemic arterial desaturation is limited to the descending aorta. Saturations in the ascending aorta, right arm, and cerebral circulation are normal.

The atrial and arterial connections are, in a sense, protective for the neonate with PPHN. If the pulmonary vascular resistance is significantly higher than systemic resistance, the right ventricle might not be able to generate the pressure required to overcome the high resistance. Without atrial or arterial connections, the output through the right side of the heart falls, and there is inadequate pulmonary blood flow, pulmonary venous return, and left ventricular filling. The result is high systemic venous (right atrial) pressure and low left atrial, left ventricular, and systemic arterial pressures. Arterial hypotension is avoided when the left atrium is filled across the foramen ovale or the aorta from the pulmonary artery. Although the result of this shunting is systemic arterial hypoxemia, the shunt does provide normal blood pressure and flow. Organ perfusion is maintained, and oxygen delivery can be nearly normal by increasing tissue extraction.

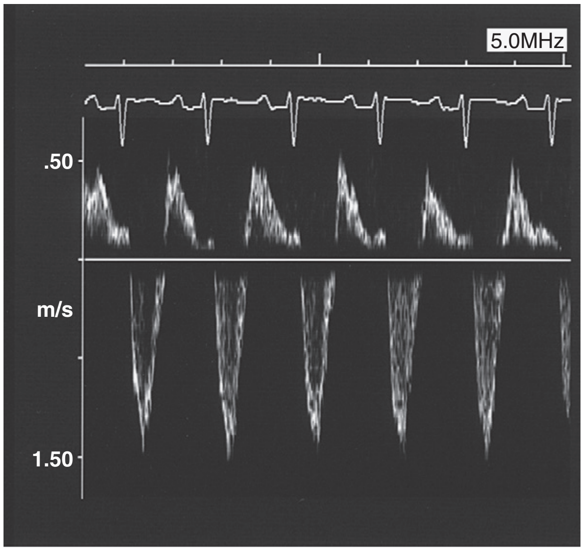

Figure 45–20. Doppler recording made in the patent ductus arteriosus of a neonate with severe persistent pulmonary hypertension of the newborn. It documents pulmonary artery to aorta (right-to-left) shunting during systole and left-to-right (above baseline) flow in diastole.

Diagnosis

The recognition of risk factors for PPHN has been one of the major diagnostic tools to differentiate babies with PPHN from those with structural heart disease. The physical examination might be of limited value. A modest right ventricular impulse and single second heart sound are features of many cyanotic heart defects. The presence or absence of a murmur is not helpful. Neonates with transposition of the great arteries do not have murmurs, and those with PPHN might have the murmur of high-velocity tricuspid regurgitation. Significant precordial hyperactivity is unusual in PPHN and suggests structural heart disease, most often total anomalous pulmonary venous return. The chest radiograph might document the parenchymal disease, which could be the triggering factor for PPHN. Evidence of pulmonary edema should suggest structural heart disease.

Preductal and postductal blood gas measurements have been used to differentiate PPHN from structural heart disease. Babies with PPHN might have nearly normal right arm oxygen tension (PaO_2) and oxygen saturations (SaO_2), but the ductal-level right-to-left shunt causes lower PaO_2 and saturation measured from an umbilical artery sample. This approach has clear limitations. If atrial-level right-to-left shunting is a prominent feature of PPHN, both the right arm and the right leg saturations will be low. Conversely, babies with patent ductus arteriosus and coarctation of the aorta might have differential cyanosis without a significant blood pressure difference. The clinical course and response to treatment are often the most valuable signs.

Because PPHN is a labile disease, documentation of normal arterial PaO_2 at some point during the course does help exclude congenital heart disease. Echocardiography can usually provide a definitive structural diagnosis. Of equal importance is the physiologic data available from Doppler studies of atrial and ductal flow. Measurement of ductal and tricuspid regurgitation velocities with simultaneous blood pressure measurement provides an accurate indication of right-sided pressures and physiology.

Treatment

The primary goal of therapy is to lower the pulmonary vascular resistance selectively. Years of experimental and empirical therapy have identified a number of effective strategies for neonates with PPHN (Table 45-7). Management of PPHN typically requires integration of therapeutic strategies simultaneously directed toward the pulmonary hypertension and, if present, the underlying lung disease. In cases of congenital diaphragmatic hernia, a small cross-sectional area of the pulmonary vessels results in high pulmonary vascular resistance.

TABLE 45–7 Proposed Treatment Strategies for Persistent Pulmonary Hypertension

Type	Proven Therapies*	Potentially Beneficial Therapies	Unproven Therapies
Pulmonary treatments	Oxygen Surfactant for RDS and meconium aspiration syndrome	High-frequency ventilation	Marked respiratory alkalosis
Pharmacologic treatments	Inhaled nitric oxide	—	Alkali infusion Other intravenous vasodilators
Cardiac support	Support of cardiac output with dopamine, fluid Normalization of ionized calcium	—	—
Environmental strategies	—	Avoidance of noise Reduced light	Paralysis
Rescue treatments	Inhaled nitric oxide Extracorporeal membrane oxygenation	—	—

*Efficacious in well-designed randomized trials.
RDS, respiratory distress syndrome.

Attempts to relieve pulmonary hypertension must be coordinated with optimal timing for surgery (see Chapter 44, Parts 5 and 8). Fetal surgical therapy for diaphragmatic hernia is addressed in Chapter 11.

Appropriate management of any underlying parenchymal lung disease must be aggressively pursued in patients with PPHN. Surfactant deficiency (or inactivation) can contribute to respiratory failure in term infants with PPHN who have nonspecific lung disease (which could be a variant of respiratory distress syndrome), meconium aspiration syndrome, or neonatal pneumonia. Exogenous surfactant therapy may improve lung function and outcome in some patients. High-frequency ventilation can optimize lung volume and enhance alveolar ventilation (see Chapter 44, Part 4). Modest respiratory alkalosis can prove useful in inducing pulmonary vasodilation.

Data from animal studies suggested that alkalosis, whether respiratory or metabolic, could lower pulmonary vascular resistance. Neonatologists quickly embraced alkali infusion as a treatment of PPHN on the assumption that hyperventilation and alkali infusion were equivalent. However, no randomized, controlled trials of either hyperventilation or alkali infusion are available. A review of a cohort of 385 newborns with PPHN indicated that a modest hyperventilation strategy might be associated less often with the need for extracorporeal membrane oxygenation or long-term oxygen than alkali administration.[70] These data, together with work on metabolic alkalosis in critically ill adults, have led many to question the role of alkali infusion.[71] A common compromise in management of PPHN is to maintain pH in the 7.4 to 7.45 range by modest hyperventilation, avoiding more severe alkalosis which can have detrimental neurodevelopmental consequences.

Pharmacologic management aims to normalize systemic pressures (e.g., dopamine) while relieving pulmonary hypertension and thus to minimize the risk for right-to-left shunting. Many vasodilators (e.g., nitroprusside, prostaglandin, isoproterenol) have been used; however, none appears to cause selective pulmonary vasodilation. Calcium channel blockers are of no benefit. Nonrandomized studies have demonstrated an improvement in PPHN in a small number of babies receiving magnesium sulfate infusion.[65] Available animal data suggest that magnesium sulfate does not have a selective pulmonary vasodilator effect.[56] The use of magnesium sulfate cannot be encouraged.

The discovery of nitric oxide's role in inducing endothelium-derived relaxation has delivered a selective modulator of pulmonary vascular resistance. Studies with low doses of inhaled nitric oxide (<20 ppm) have suggested that the number of babies requiring extracorporeal membrane oxygenation to survive PPHN is reduced by 40% (see Chapter 44, Part 8). A randomized, controlled trial of high-frequency ventilation and inhaled nitric oxide suggested that the combination was more effective than either treatment individually.[33] The apparent toxicity of nitric oxide appears to be low. Concerns about downregulation of endogenous nitric oxide synthesis, effects on bleeding time, and pulmonary immune function have been raised in early experimental studies but have been significant in clinical use.

Preliminary experience with intravenous sildenafil (inhibitor of cGMP-specific phosphodiesterase) has demonstrated improved oxygenation in neonates with PPHN, many of whom were already receiving inhaled nitric oxide. The most commonly reported adverse event was hypotension. A randomized clinical trial will be needed to determine if there is a therapeutic role for this therapy.[62a]There has been a broad and favorable experience with continuous intravenous infusion of prostacyclin for treating pulmonary hypertension in children and adults.[4,5] The experience in neonates is limited but encouraging, and it can emerge as a treatment in selected neonates with chronic pulmonary hypertension.[17] The dose of prostacyclin used in the Eronen and associates study,[17] a mean dose of 60 ng/kg per minute, was higher than that typically used for older children, and unlike studies in older children, it was used for only a few days. The experience with the oral prostacyclin analogue in children is limited; however, studies in adults with primary pulmonary hypertension suggest a long-term benefit of this drug.[27,44]

MYOCARDIAL DISEASES: CARDIOMYOPATHY AND MYOCARDITIS

Cardiomyopathy refers to a diverse group of myocardial diseases with multiple causes. Definition and classification of cardiomyopathy are hampered by this diversity and uncertain pathogenesis. Because cardiomyopathy could be familial, these diseases have been the focus of intense metabolic and, most recently, genetic research to uncover the molecular basis of cardiomyopathy. Myocarditis, an inflammatory, usually infectious, process affecting the myocardium, can cause a cardiomyopathy (see Chapter 50).

Congestive or dilated cardiomyopathies are diseases in which there is both ventricular dilation and systolic dysfunction. The myocardial dysfunction in dilated cardiomyopathy could be due to primary disorders of the myocardium or to abnormalities of coronary perfusion (coronary embolism), afterload (hypertension, aortic stenosis), or arrhythmia (persistent supraventricular tachycardia). Fetal or neonatal congestive heart failure usually occurs when there is significant myocardial impairment. Poor perfusion and pulses with respiratory distress are present shortly after birth. Babies are initially well, but during the first weeks of life have either a sudden insult such as a coronary embolism or previously unrecognized and compensated myocardial dysfunction, which is worsened by an intercurrent infection or stress. Clinical clues to milder forms of cardiomyopathy include loud third heart sounds and the murmur of mitral regurgitation. Myocarditis causing cardiomyopathy should be suspected when there is a history of maternal infection, in babies with ST-T segment changes on the electrocardiogram, or in those with pancarditis (pericardial effusion, atrioventricular valve regurgitation, and myocardial dysfunction) by echocardiography.

Hypertrophic cardiomyopathies are structural abnormalities of the myocardium in which ventricular mass is out of proportion to the afterload of the ventricle. The process usually involves the left ventricular walls and is either asymmetric or concentric. Either asymmetric or concentric hypertrophic cardiomyopathies can be obstructive and nonobstructive. The left ventricular cavity could be either normal in size or small. The primary physiologic abnormality is ventricular diastolic dysfunction. Babies with obstructive hypertrophic cardiomyopathy have the additional problem of systolic obstruction to left ventricular ejection. In babies with primary disorders of the myocardium, hypertrophy and myofibrillar disarray could be the result of mutations of the proteins of the cardiac sarcomere.[38,42] Severe hypertrophic cardiomyopathies with impaired systolic function should suggest the possibility of inherited genetic abnormalities from both parents.[73] Babies with storage diseases could have features similar to hypertrophic cardiomyopathy with thickening of the myocardium because of infiltration of the muscle. They might not have the normal or hyperdynamic systolic function that is present with primary hypertrophic cardiomyopathy. The myopathy seen in infants of diabetic mothers is the most common form of hypertrophic cardiomyopathy seen in the neonatal period (see Chapter 16 and Chapter 49, Part 1).

Restrictive cardiomyopathy is characterized by impairment of diastolic filling, usually with normal systolic function. The result is atrial dilation and normal ventricular size. Isolated restrictive cardiomyopathy is rare in the neonate. However, babies with the contracted form of endocardial fibroelastosis have a significant restrictive cardiomyopathy caused by the scarring of the endocardium. This disease is manifested in the first few months of life with congestive heart failure caused by the diastolic dysfunction. Systolic function is usually near normal.

Diagnosis

The approach to neonates with suspected cardiomyopathy or myocarditis must include a methodical approach to the diagnosis (Boxes 45-11 to 45-13)* and a level of support appropriate for their clinical symptoms. The inclusion of a myocardial, skin, or skeletal muscle biopsy as part of the examination of the baby with cardiomyopathy should be guided by the clinical course and the results of the initial blood and urine tests. The myocardial biopsy can guide therapy or help in defining the prognosis by identifying pathologic features by light and electron microscopy, by searching for viral ribonucleic acid, or by using new techniques for assessing mitochondrial function.[55] Evidence of active inflammation or immune suppression can be treated with intravenously administered immune globulin, although its role in the treatment of myocarditis remains to be fully validated.[16,26] The prognosis is often good if the baby can be managed through an episode of myocarditis. In contrast, if a biopsy shows endocardial fibroelastosis or the echocardiogram shows endocardial thickening, the likelihood of recovery of myocardial function is small.

Treatment

Babies with dilated cardiomyopathy and minimal symptoms can be successfully managed with digoxin, diuretics, and captopril. Those with poor cardiac output are initially supported with mechanical ventilation, intravenous inotropes, and afterload reduction, and then the transition to oral agents is made. Ventricular and atrial arrhythmias are poorly tolerated in babies with severe myocardial dysfunction and must be effectively treated (see the discussion of arrhythmias in Part 9). Shock with acidosis and organ dysfunction is an indication for extracorporeal membrane oxygenation, especially if the cause is reversible or if transplantation is being considered.

CARDIAC TUMORS

Cardiac tumors can be identified on fetal echocardiography or on evaluation of murmurs or arrhythmias. The most common neonatal tumors are rhabdomyomas, and some babies have tuberous sclerosis.[29] Rhabdomyomas arise on the ventricular endocardial surface, and if they are large enough, they can interfere with ventricular filling or emptying. When they are located near the atrioventricular valves, the tissue can serve as a bypass tract and mimic the features of Wolff-Parkinson-White syndrome.[41] Confirmation by myocardial biopsy in a

BOX 45–11 Causes of Dilated Cardiomyopathy in Infants

MYOCARDITIS
Viral: Coxsackie virus group B, parvovirus, adenovirus
Bacterial: group B streptococcal sepsis

ENDOCARDIAL FIBROELASTOSIS
Primary: in utero myocarditis or infarction
Secondary: critical aortic stenosis

NEONATAL AND INFANT MYOCARDIAL INFARCTION
Amniotic fluid embolus, air embolus, clot
Protein C, protein S deficiency
Homocystinuria
Origin of left coronary artery from pulmonary artery

ARRHYTHMIAS
Incessant atrial or ventricular tachycardia

STORAGE DISORDERS
Glycogenesis type IIa (Pompe disease, acid maltase deficiency)*
Infantile glycogenesis type IV (debrancher deficiency with phosphorylase deficiency)
Cardiac glycogenesis (cardiac phosphorylase kinase deficiency)
G_{M2}L: gangliosidosis with ascites (β-galactosidase deficiency)
G_{M2}: gangliosidosis (hexosaminidase deficiency)

CARNITINE DEFICIENCY*
Renal tubular and gastrointestinal wasting of carnitine[28]
Neonatal transient carnitine deficiency

MITOCHONDRIAL DISEASES
NADH dehydrogenase (cytochrome complex I) defect
Cytochrome c oxidase (cytochrome complex IV) defect
Coenzyme Q cytochrome c reductase (cytochrome complex III) defect

X-LINKED MITOCHONDRIAL DISORDERS
Barth syndrome[9,22]
Type II X-linked 3-methylglutaconic aciduria[47]
Thiamine-responsive defects in oxidative phosphorylation

MYOSIN MUTATIONS
Mutation of mtDNA in the tRNA (Leu[UUR]) gene[61]

MISCELLANEOUS
Congenital adrenal hyperplasia*
Selenium deficiency

---

*Could have features of hypertrophic myopathy.
mtDNA, mitochondrial DNA; NADH, nicotinamide adenine dinucleotide, reduced; tRNA, transfer ribonucleic acid.

BOX 45–12 Hypertrophic Cardiomyopathy

Infant of a diabetic mother
B cell adenoma[25]
Beckwith-Wiedemann syndrome
Noonan syndrome[59]
Dexamethasone or ACTH therapy[30]
Familial: chromosomes 1, 14, and 15[64]
Mitochondrial disorders
Carbohydrate-deficient glycoprotein syndrome[11]
Congenital cataracts and hypertrophic cardiomyopathy
Barth syndrome[51]

ACTH, adrenocorticotropic hormone.

BOX 45–13 Laboratory Studies to Be Considered in Infantile Cardiomyopathy of Suspected Metabolic Origin

BLOOD
Carnitine
Amino acids
Blood gases
Lactate, pyruvate
Leukocyte preparations for enzyme assays
Genetic testing for mutations of the cardiac sarcomere

Fibroblast cultures for specific enzymatic studies

MUSCLE BIOPSY
Morphologic studies for skeletal myopathy
Biochemical studies for carnitine deficiency and mitochondrial disorders

MYOCARDIAL BIOPSY
Light and electron microscopy
Viral ribonucleic acid
Mitochondrial function

symptom-free neonate is not necessary, especially if the skin and central nervous system features of tuberous sclerosis are present. Rhabdomyomas typically regress,[39] and surgical excision is not needed unless the tumor is obstructing flow and is discrete or pedunculated enough to allow excision. Radiofrequency ablation of the tumors has been successfully performed for medically resistant arrhythmias.

Other rare tumors that can occur in the neonate include myocardial hemangioma,[6] hamartoma,[37] fibroma, and pericardial teratomas. Myocardial hemangiomas are tumors with dense capillary beds which can have connections to the coronary arteries. They are on the epicardial surface with intrusion into the myocardium. Hemangiomas can cause subpulmonary stenosis if they are located in the right ventricular outflow tract. Small hamartomas cause histiocytoid or oncocytic cardiomyopathy, which is associated with severe and persistent ventricular arrhythmias. Myocardial fibroma can be located in the myocardium or on the atrial wall or can involve the mitral valve and cause obstruction (Fig. 45-21). Intrapericardial teratoma is a benign tumor attached to the base of the aorta. It is associated with mediastinal compression and pericardial effusion in the fetus, neonate, or young infant. Successful excision of intrapericardial teratoma has been reported, although large tumors can

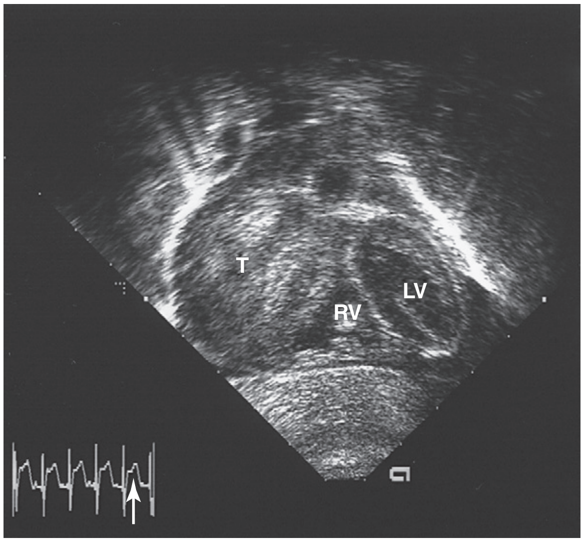

Figure 45–21. Subcostal echocardiogram of symptom-free 2-week-old infant with murmur. A large tumor (T) nearly completely filled the right ventricle (RV). The tumor was successfully excised and histologic study showed fibroma. LV, left ventricle.

cause fetal death. Atrial myxomas are not reported in the neonatal period.

A redundant eustachian valve or Chiari network in the right atrium might be mistaken for an atrial tumor. Atrial masses in neonates with a history of central venous catheters probably represent thrombi. Bacterial or fungal infection of these thrombi is a frequent concern, although excision of the masses is unusual. Thrombi beginning in the superior or inferior vena cava can be difficult to extract successfully once they have begun to organize. Thrombolysis carries risk for bleeding and seldom dissolves a clot that has been present for more than a few days. Similarly, anticoagulation has uncertain benefit, unless there is a documented increase in the thrombus size. Embolization of a right atrial thrombus rarely occurs, even when it appears to be highly mobile and pedunculated.

VASCULAR RINGS

In the first month of life, respiratory distress caused by vascular rings usually indicates severe obstruction. Severe obstruction is caused by either a double aortic arch or a pulmonary artery sling. Neither left aortic arch with aberrant right subclavian artery nor right aortic arch with aberrant left subclavian artery and right ductus arteriosus causes a ring or obstruction. Right aortic arch with aberrant left subclavian artery and left ductus arteriosus does form a ring, but symptoms in the neonatal period are unusual. Diagnosis of these arch abnormalities can be made on the basis of a combination of echocardiography, barium swallow radiography, computed tomography, and magnetic resonance imaging (see Chapter 44, Part 5).

Several variants of double aortic arch should be considered as part of the presurgical assessment. The dominant arch should be preserved and the smaller or atretic side divided. Both a right and a left ductus might be present, and coarctation of the aorta has been reported with double aortic arch. Any of these variants produces the bilateral and posterior indentation on the esophagus seen by barium swallow radiography. Echocardiography and magnetic resonance imaging do not identify any atretic segments. The atretic side is inferred by the origin of the arch vessels on the atretic side (usually the left) from an anterior and a posterior aortic diverticulum. Coarctation of the aorta must be identified by imaging because the Doppler or magnetic resonance flow disturbances are not present until the arch is divided. Careful color flow Doppler mapping should permit identification of the location of either a right or left patent ductus arteriosus. There is considerable experience with surgical division of the vascular rings[1,3,10] and with video-assisted thoracoscopic surgery in older children.[34]

Pulmonary artery sling is caused by the origin of all or part of the left pulmonary artery from the right pulmonary artery. The aberrant pulmonary artery courses posteriorly between the trachea and esophagus and along the left main bronchus. Diagnosis is suggested by the echocardiogram and the distinctive anterior impression on the esophagus on a barium swallow radiograph. Pulmonary artery sling occurs as an isolated defect or in association with ventricular septal defect. Mobilization and reimplantation of the left pulmonary artery help relieve the obstruction; however, tracheomalacia or tracheal rings can cause persistent respiratory distress.

PERICARDIAL EFFUSION

Pericardial effusion is seen in neonates who have had fetal congestive heart failure caused by anemia or myocarditis. Small effusions may be associated with neonatal pneumonia. Effusions can also occur after open heart surgery and as a complication of hyperalimentation with central venous catheters as a result of local irritation of the atrial or superior vena caval wall by fluids with high osmolality. Pneumopericardium is a complication of mechanical ventilation and can have hemodynamic effects similar to those of fluid. If the pericardial fluid accumulated gradually, intrapericardial pressure remains low and symptoms are few until the effusion is large. Rapid accumulation of fluid, either blood or intravenous fluid, can cause pericardial tamponade with much smaller volumes.

The diagnosis of pericardial tamponade should be suspected in any baby with early signs of poor cardiac output, including tachycardia and poor perfusion. Pulsus paradoxus, an exaggerated fall in blood pressure with inspiration, is easiest to observe in neonates with arterial lines for continuous blood pressure monitoring. A dramatic increase in heart size on a chest radiograph supports the clinical diagnosis. Intrapericardial air is usually obvious on the radiograph and can be differentiated from mediastinal air because it encircles the heart. Echocardiography is the best way to confirm the diagnosis and assess the physiologic impact of the effusion. Diastolic collapse of the right atrium and right ventricle suggests a significant effusion. Pericardiocentesis by the subxiphoid approach can drain enough fluid or air to relieve symptoms. If the fluid or air returns, a small catheter can be placed percutaneously or surgically.

NEONATAL MARFAN SYNDROME

In the absence of a known familial genotype, the clinical diagnosis of Marfan syndrome in the neonate who has an affected parent requires a careful multisystem evaluation, including echocardiography to assess aortic root dimension. The diagnosis is usually difficult to establish in neonates referred for evaluation solely on the basis of their family history. Aortic root dimensions are usually within the normal range, and mitral valve prolapse is absent. This is in contrast to the neonates with dramatic multisystem involvement, who nearly always represent new mutations.[19,43] Skeletal features are recognizable, and clinical signs of congestive heart failure caused by mitral or tricuspid regurgitation could be evident in the first days of life. Aortic root dimensions are often increased, and aortic regurgitation can be seen by color flow mapping. Genetic testing to exclude Loeys-Dietz syndrome may also be indicated in the neonate presenting with physical findings of connective tissue abnormalities.[36]

Medical management of the mitral regurgitation might improve symptoms, but early mitral valve repair is often needed. Aortic root dilation must be carefully followed and elective aortic root replacement performed if aortic dilation becomes severe.[18] Multicenter studies are underway to evaluate the relative benefit of beta blockade or angiotensin receptor blockade to slow the progression of the aortic root enlargement and permit surgery at a later time.[48]

THE PREMATURE BABY WITH CONGENITAL HEART DISEASE

Patent ductus arteriosus is obviously the most prevalent heart defect in the premature baby. The clinical recognition, echocardiographic assessment, medical management, and when needed, surgical management, are well established and are effective even in the baby weighing 500 g. A population-based study suggests that cardiovascular defects, in general, may be more prevalent in preterm babies despite the assumption that most defects are well tolerated in utero.[63] Many defects in preterm babies are not hemodynamically important and do not require specific management. For preterm babies with cyanotic heart defects, large ventricular septal defects, or left heart obstruction, the nutritional and respiratory needs of the premature baby can dramatically add to the challenge of a congenital heart defect. The initial pulmonary vascular resistance in a premature baby may be lower because of less well developed muscular arterioles, which can lead to early signs of congestive heart failure in babies with defects causing excessive pulmonary blood flow.

Case reports of successful surgical or interventional catheterization of a number of defects in premature babies weighing between 1 and 2 kg certainly indicate that these babies can be helped. Reddy and colleagues reviewed their experience with heart surgery in 102 newborns weighing between 700 and 2500 g (including 16 weighing less than 1500 g).[53] The overall mortality was 18%, but many babies were successfully treated. Long-term infusion of prostaglandin E_1 in babies with cyanotic or left heart defects does permit a period for maturation of the lungs and nutrition and, for many premature babies, is preferable to open heart surgery in those weighing less than 1800 g. The risk that pulmonary vascular disease will develop within several months, even in a baby with truncus arteriosus or transposition of the great arteries, is small. The most important risk of conservative management is the occurrence of necrotizing enterocolitis. If heart failure or hypoxia is unmanageable, palliation or correction can be undertaken. Defects with atrioventricular valve regurgitation, severe aortic stenosis, and defects with pulmonary venous obstruction are difficult to manage medically and are probably more likely to have a good outcome with aggressive surgical or catheter therapy. Associated bronchopulmonary dysplasia also increases the risk associated with surgical treatment.[40]

PART 9

Neonatal Arrhythmias

George F. Van Hare

The diagnosis and treatment of cardiac arrhythmias in neonates can be challenging and often different from diagnosis and treatment of the same arrhythmias in older children. For example, infants can sustain very fast sinus rates, and so sinus tachycardia may masquerade as paroxysmal supraventricular tachycardia. The neonatal normal range of electrocardiographic values must be considered when one is interpreting electrocardiograms. Also, the natural history of arrhythmias occurring in the neonatal period is often dramatically different from those occurring later in life.

METHODS OF DIAGNOSIS

Heart Rate

The observation of an abnormal heart rate can be the first sign of an arrhythmia, yet determining the exact heart rate is often difficult. The pulse might be too fast to count by palpation or auscultation. Bedside cardiac monitors that automatically display the heart rate as a digital read-out might oversense or undersense the QRS complex, yielding incorrect values. Pulse oximeters count only the beats that produce an appreciable pulse and so may underestimate actual heart rate, and they are prone to artifact. The most accurate method is to determine the rate from an electrocardiogram. All QRS complexes are counted for a period of 6 seconds, and the rate per minute is obtained by multiplying by 10. The only pitfall of this method is machine malfunction causing paper drag, which results in a slower paper speed and a more rapid apparent heart rate.

Electrocardiogram

Although some arrhythmias can be diagnosed directly from the cardiac monitor, analysis of a paper record of the electrocardiogram is the standard for accurately diagnosing arrhythmias. Small variations in the PR or R-R interval are detectable only with the paper record. The manner of initiation and termination of tachycardias, the morphology and duration of the QRS complex, and the P wave configuration determined from the electrocardiogram are important diagnostic features of arrhythmias. All electrocardiograms of interest should be preserved for later analysis and consultation because future treatment decisions are often made on the basis of these recordings.

Similarly, cardiac monitors employing three or four chest electrodes provide a great deal of information, but details such as P wave axis, QRS complex duration, and ST segment morphologic features are best evaluated by the pediatric standard 15-lead electrocardiogram (the standard 12 leads plus V_{3R}, V_{4R}, and V_7). Therefore, when time and hemodynamic condition allow, it is important to obtain a complete 15-lead electrocardiogram.

Ambulatory Monitoring and Telemetry

Conventional neonatal monitors and electrocardiograms offer brief opportunities to record the heart rhythm. For the neonate with a sustained arrhythmia, these technologies are usually adequate and may be diagnostic. For the neonate with intermittent symptoms or rhythm disorders, continuous recording of the rhythm with the ability to analyze the range of heart rates and the onset and cessation of arrhythmias is invaluable for diagnosis and management. Continuous monitoring is available either in inpatient full-disclosure telemetry units or with portable ambulatory electrocardiography (Holter monitoring).

Esophageal Electrocardiogram

The atrial electrogram can be recorded by passing a flexible bipolar electrode down the esophagus and positioning it behind the left atrium. These leads are connected to a filtering box and recorded with simultaneous limb and chest leads. The amplitude of the transesophageal atrial electrogram is larger than the surface P wave. The atrial electrogram can be compared with the QRS complex on the simultaneous surface electrocardiogram or with ventricular electrograms from the transesophageal lead. The atrium can also be paced by this electrode, and transesophageal pacing can be used to terminate various types of reentrant tachycardias.

Electrophysiologic Testing

Formal transvenous electrophysiologic studies to elucidate the mechanisms of arrhythmias or to guide treatment of arrhythmias are rarely necessary in the neonatal period. Limited but often diagnostic studies can be performed with the temporary atrial and ventricular epicardial pacing wires placed at the time of open heart surgery. These wires are used for recording the atrial and ventricular electrograms and for pacing to assess the conduction system and to terminate atrial tachycardias.

Blood Pressure

Automatic blood pressure monitors are convenient and provide accurate blood pressure determinations in most neonates with arrhythmias. Some devices function poorly in babies with tachycardia, particularly at rates seen in the neonate. Intra-arterial blood pressure monitoring is the most accurate technique for measuring blood pressure in the neonate who has poor cardiac output and an arrhythmia.

MECHANISMS OF TACHYCARDIA

General Mechanisms

The two general mechanisms for tachyarrhythmias seen in clinical practice (Tables 45-8 and 45-9) are reentry and increased automaticity. Reentry is the circular movement of electrical impulses within the atrium, atrioventricular (AV)

TABLE 45–8 Mechanisms of Tachycardia with Normal QRS Duration

Diagnosis	Findings on Electrocardiogram
Reentrant Tachycardias	
Atrial and sinoatrial reentry	P waves present, precede next QRS complex Terminates with QRS rather than P wave Variable AV conduction possible; AV block does not terminate atrial rhythm P wave axis superior or inferior, depending on origin
Atrial flutter	Sawtooth flutter waves AV block does not terminate atrial rhythm Atrial rate up to 500 beats/min in neonates Variable AV conduction is common
Tachycardia mediated by accessory pathway (WPW syndrome and concealed accessory pathway)	P waves follow QRS, typically on upstroke of T wave Superior or rightward P wave axis AV block always terminates tachycardia Typically terminates with P wave After termination, those with WPW syndrome have pre-excitation
Permanent form of junctional reciprocating tachycardia	Incessant P waves precede QRS complex Inverted P waves in leads II, III, aVF AV block always terminates tachycardia May terminate with QRS complex or with P wave No pre-excitation after termination
Atrioventricular node reentry	P waves usually not visible; superimposed on QRS complex AV block usually terminates tachycardia
Atrial fibrillation (probably reentrant)	Irregularly irregular; no two R-R intervals exactly the same P waves difficult to see or bizarre and chaotic
Increased Automaticity Tachycardias	
Sinus tachycardia	Normal P wave axis P waves precede QRS Causes: extrinsic factor such as heart failure, fever, anemia, catecholamine, or theophylline infusion Continue in presence of AV block
Atrial ectopic tachycardia	Incessant Abnormal P wave axis that predicts location of focus P waves precede QRS Continues in presence of AV block
Junctional ectopic tachycardia	Incessant Usually with atrioventricular dissociation and slower atrial than ventricular rate Capture beats with no fusion

AV, atrioventricular; WPW, Wolff-Parkinson-White.

TABLE 45–9 Mechanisms of Tachycardia with Prolonged QRS Duration

Diagnosis	Findings on Electrocardiogram
Ventricular tachycardia	Often with AV dissociation Capture beats with narrower QRS complex than on other beats Fusion beats
Supraventricular tachycardia with preexisting bundle branch block	QRS morphologic features similar to those of sinus rhythm QRS morphologic features are those of right or left bundle branch block
Supraventricular tachycardia with rate-dependent bundle branch block	QRS morphologic features usually similar to those of right or left bundle branch block Rare in small children Difficult to distinguish from ventricular tachycardia in children
Antidromic supraventricular tachycardia in WPW syndrome	QRS morphologic features similar to those of pre-excited sinus rhythm but wider, never with AV dissociation
Atrial fibrillation with WPW syndrome	Irregularly irregular wide QRS tachycardia

AV, atrioventricular; WPW, Wolff-Parkinson-White.

node, or ventricles. Reentrant tachycardias include sinoatrial and intra-atrial reentry, AV node reentry, AV reciprocating tachycardia involving an accessory pathway, atrial flutter, the permanent form of junctional reciprocating tachycardia (PJRT), and the reentrant form of ventricular tachycardia. Increased automaticity is the abnormal state in which cardiac cells display autonomous repetitive depolarization at a rate faster than normal. Automatic tachycardias include sinus tachycardia, atrial ectopic tachycardia (AET), junctional ectopic tachycardia (JET), and the automatic focus form of ventricular tachycardia.

Three conditions are needed o support reentrant tachycardias. First, an anatomically distinct reentrant circuit must be present, allowing for the circular movement of excitation. Second, unidirectional conduction block must occur, allowing subsequent reversed conduction in that segment. Third, there must be an area of conduction delay in the reentry circuit sufficient to allow recovery of all components of the circuit before the arrival of the next wave of activation.

The definitive example of a reentrant supraventricular tachyarrhythmia is the reciprocating AV reentrant tachycardia in babies with Wolff-Parkinson-White syndrome. Typically, a premature atrial contraction blocks in the accessory pathway but is conducted with a significant delay down the AV node and His-Purkinje system. Impulses arriving in the ventricle are then conducted retrograde in the accessory pathway back to the atrium. The conduction delay in the AV node allows the accessory pathway and atrium sufficient time to recover and thus allows establishment of the tachycardia. Orthodromic tachycardias use the AV node for anterograde conduction, and antidromic tachycardias use the AV node for retrograde conduction.

A major characteristic of the reentrant tachycardias that helps differentiate them from the automatic tachycardias is their tendency to start and stop suddenly. Premature atrial and ventricular contractions can initiate or terminate these rhythms. Direct-current cardioversion is usually successful in terminating reentrant tachycardias but not automatic focus tachycardias.

Specific Mechanisms

SINUS TACHYCARDIA

Sinus tachycardia can masquerade as a paroxysmal supraventricular tachycardia in neonates. Sinus tachycardia is nearly always secondary to some other problem. Identification and treatment of that problem can facilitate the diagnosis of sinus tachycardia. For example, gradual slowing of a narrow QRS tachycardia after an intravenous fluid bolus in a hypovolemic neonate provides strong evidence for sinus tachycardia and against other forms of paroxysmal supraventricular tachycardia. Other causes of sinus tachycardia include heart failure, high fever, pain, hypoxia, exogenous chronotropic agents such as isoproterenol or dobutamine, xanthine therapy, undersedation in paralyzed infants supported by mechanical ventilation, or rarely, hyperthyroidism.

The criteria for sinus tachycardia are normal P wave axis, gradual onset and termination, and rates less than 250 beats per minute. Narrow-complex tachycardias with rates between 180 and 250 beats per minute can be either sinus tachycardia or some form of abnormal tachycardia.

The correct diagnosis must be established, if possible, before antiarrhythmic therapy is instituted. This can be difficult because in infants, the P wave often is partially superimposed on the preceding T wave. Several leads should be carefully analyzed for deformation of the T wave by a P wave.

Vagal maneuvers and other methods of converting supraventricular tachycardia will not terminate sinus tachycardia. Vagal maneuvers can briefly slow the rhythm, but because the underlying cause of sinus tachycardia is unaffected by such maneuvers, the rhythm resumes immediately. Therapy should be directed to the likely underlying causes of the sinus tachycardia. The response to such measures could well be diagnostic.

ACCESSORY PATHWAY REENTRANT TACHYCARDIA

Wolff-Parkinson-White syndrome is seen in neonates with structurally normal hearts and those with heart defects. The most common defect is Ebstein malformation of the tricuspid valve; as many as 25% of these patients have an accessory pathway.[12]

Wolff-Parkinson-White syndrome is caused by an accessory pathway electrically connecting the atrial tissue and the ventricular tissue. Neonates with manifest Wolff-Parkinson-White syndrome have a delta wave or other evidence of pre-excitation on a baseline electrocardiogram in sinus rhythm. Neonates with concealed accessory pathways do not have manifest pre-excitation, and anterograde conduction is absent in the accessory pathway. In both cases, orthodromic tachycardia typically is elicited by a premature atrial or ventricular contraction, proceeds with conduction down the AV node and His-Purkinje system, and continues up the accessory pathway to the atria to complete the reentrant circuit. In rare neonates with antidromic tachycardia, the accessory pathway is used for anterograde conduction, and the AV node or a second accessory pathway is used for retrograde conduction.

During orthodromic tachycardia, there is no delta wave. The tachycardia rate is typically 250 to 300 beats per minute in infants. Because of brisk AV conduction, the P waves can fall halfway between the QRS complexes or can be difficult to discern on the T wave (Fig. 45-22). There is little or no variation in the R-R interval, and because the AV node is part of the reentry circuit, AV block always terminates the tachycardia, for at least several beats, although immediate reonset is often seen. If bundle branch block develops during the tachycardia in the same ventricle as the accessory pathway, the ventriculoatrial time lengthens, and the tachycardia rate often slows. In antidromic tachycardia, the ventricle is activated entirely from the accessory pathway so that QRS complexes are wide. P waves can be seen just before the wide QRS complexes.

Differentiation of antidromic tachycardia with bundle branch block from ventricular tachycardia can be clarified by analyzing the relationship between atrial and ventricular activation. AV dissociation excludes reentrant tachycardia depending on an accessory pathway in either direction and suggests ventricular or junctional tachycardia.

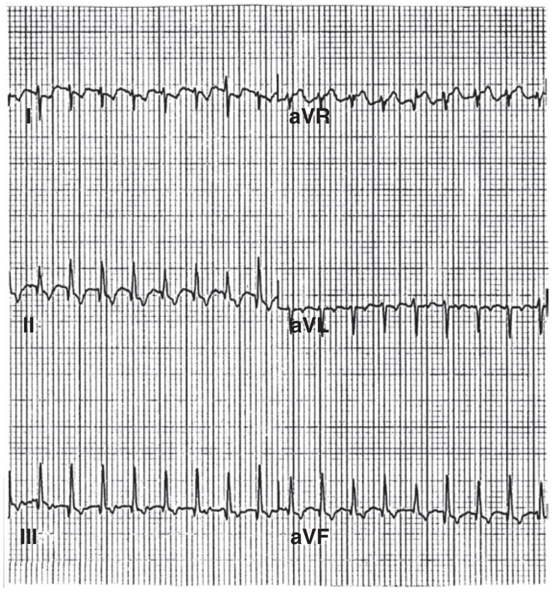

Figure 45–22. Six-lead electrocardiogram in an infant with accessory pathway tachycardia. Note suggestion of P waves superimposed on upstroke of T waves, best seen in lead II.

PERMANENT FORM OF JUNCTIONAL RECIPROCATING TACHYCARDIA

A related form of accessory pathway tachycardia is PJRT. The rhythm is due to a concealed slow-conducting accessory pathway, usually in the posterior-septal region. The slow retrograde accessory pathway conduction makes consistent AV node conduction possible by the time the impulse reaches the atrium through the accessory pathway. Therefore, the tachycardia in PJRT is relatively incessant, or “permanent.” Left ventricular dysfunction and even congestive heart failure, believed to be due to chronic tachycardia, have developed in infants with PJRT and persistently high ventricular rates.[9]

In PJRT, the slow retrograde accessory pathway conduction causes the P wave to be located nearer the subsequent QRS complex than the previous one. Spontaneous terminations can occur with block in either the pathway or the AV node; thus, these rhythms can end with either a P wave or a QRS complex. Because of the incessant nature of these rhythms and the location of the P wave, a misdiagnosis of incessant atrial tachycardia or even sinus tachycardia is often made. The P wave axis, however, should be superior (i.e., negative P waves in leads II, III, aVF) rather than inferior, as it would be in sinus tachycardia.

ATRIOVENTRICULAR NODE REENTRANT TACHYCARDIA

AV node reentrant tachycardia (AVNRT) is due to reentry involving dual pathways in the AV node: one fast pathway, generally with a long effective refractory period (ERP), and one slow pathway with a shorter ERP. During normal sinus rhythm, both pathways simultaneously conduct, and the impulse from the fast pathway arrives first in the bundle of His. Tachycardia is initiated when a premature atrial contraction is blocked in the fast, long ERP pathway. It is conducted through the slow pathway, and if the conduction delay is long enough, it allows enough time for the fast pathway to recover and permit retrograde conduction. This establishes the reentrant circuit and tachycardia. In neonates, AVNRT could also be initiated by sudden sinus slowing followed by a junctional escape beat or by a premature ventricular beat.

In the usual form of AVNRT, the reentrant circuit is made up of conduction down the slow pathway and up the fast pathway. Because transit from the distal node up the fast pathway to the atria takes about as long as transit from the distal node to the ventricles, the P waves are superimposed on the QRS complex and are usually not easily discernible on the surface electrocardiogram. In some children, the P wave might be visible slightly before the QRS complex. The reason is that in children, the fast AV node pathway is fast enough so that it is traversed retrograde more rapidly than the distal conduction system is traversed anterograde. In the typical form of AVNRT, the P wave originates in the low atrial septum at the site of the AV node, and the retrograde conduction produces a superior P wave axis. There is little or no variability in R-R intervals. The tachycardia starts and terminates suddenly. AV block, occurring spontaneously or induced by vagal maneuvers or medication, should with rare exception terminate the tachycardia. The rhythm could terminate with a P wave or QRS complex, depending on the site of block.

In the unusual form of AVNRT, conduction is up the slow pathway and down the fast pathway. Because conduction up the slow pathway to the atria takes longer than conduction to the ventricles, the P waves are discernible, usually closer to the subsequent QRS complex than to the previous QRS complex.

In general, AVNRT is thought to be quite rare in neonates, but accessory pathway tachycardia is much more common.

ATRIAL FLUTTER

Atrial flutter results from reentry involving a circuit in a large part of atrial muscle. Atrial flutter rates are as high as 400 to 500 beats per minute in newborn infants, in contrast with older children and adults, who normally have atrial rates of about 300 beats per minute. Atrial flutter can be seen in neonates without associated heart defects and in those with atrial dilation caused by AV valve stenosis or regurgitation.

The neonatal AV node cannot conduct atrial rates of 400 to 500 beats per minute in a 1:1 relationship, and so there is some degree of AV block. If every other atrial beat is conducted, there is 2:1 AV conduction; if every third beat is conducted, there is 3:1 conduction. The degree of AV block can vary, or there could be variable Wenckebach conduction leading to changes in the atrial and ventricular conduction intervals. In neonates with 2:1 conduction, the characteristic sawtooth appearance of flutter waves can be difficult to recognize because of superimposition on the QRS complex and the T waves. Examining multiple leads, especially leads II, III, and aVF, can facilitate the diagnosis. Episodes of increased AV block (spontaneously occurring or induced by vagal maneuvers or medication) do not usually terminate atrial reentrant tachycardias because the AV node is not part of the reentrant circuit. However, such episodes are helpful in making the diagnosis (Fig. 45-23).

The variable R-R intervals resulting from variable AV conduction can mimic the irregular R-R intervals seen in atrial fibrillation and may also cause bundle branch aberration, with some QRS complexes wider than others. Differentiation of atrial flutter from atrial fibrillation can be aided by analysis of the atrial electrocardiogram recorded from an esophageal lead or from atrial temporary pacing wires. Atrial flutter starts suddenly, stops suddenly, and ends with a QRS complex rather than a P wave, because AV block is not necessary for termination.

ATRIAL ECTOPIC TACHYCARDIA

The mechanism of AET likely involves a site with abnormal automaticity somewhere in the right or left atrium. Atrial rates range from slightly faster than normal sinus rates up to 300 beats per minute. Although neonates with AET occasionally have symptoms, this rhythm is more often incessant and causes symptoms only after weeks or months of accelerated ventricular rates. Congestive heart failure develops because of dilated cardiomyopathy. This constellation is termed *tachycardia-induced cardiomyopathy*, and it is believed that the sustained ventricular rates are directly responsible for the myocardial damage. Neonates with symptomatic AET might have had fetal tachycardia, and AET is one mechanism for nonimmune hydrops fetalis.

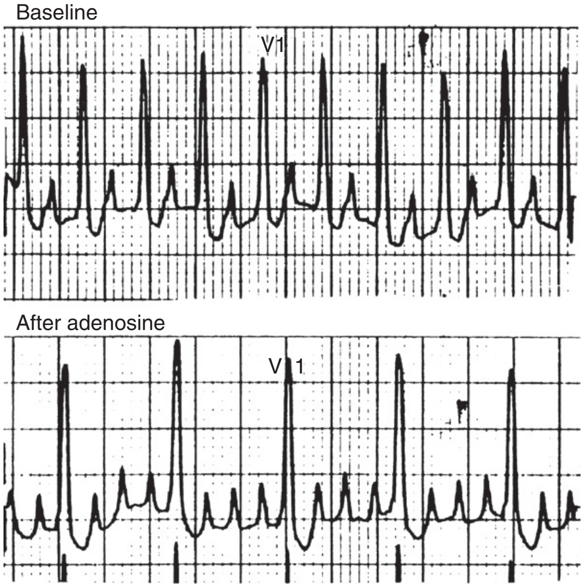

Figure 45–23. Atrial flutter in newborn infant. *Top,* P waves are not clearly discernible. *Bottom,* After administration of adenosine intravenously, flutter waves with rate of 400 beats/min are easily seen.

The most important characteristics of AET are an abnormal P wave axis and morphologic features together with an accelerated rate. Often the PR interval is prolonged, and episodes of Wenckebach conduction can occur. The continuation of the tachycardia despite AV block strongly suggests that the mechanism does not involve the AV node. In an infant with dilated cardiomyopathy and any degree of tachycardia, the P waves must be carefully examined to determine whether they are sinus or ectopic waves. This can be a difficult task, particularly when rapid rates cause superimposition of P waves on T waves. In this case, waiting for a spontaneous Wenckebach cycle or administering adenosine to produce transient AV block allows examination of a nonsuperimposed P wave. The location of the atrial focus can then be predicted on the basis of the P wave axis. For example, P waves that are inverted in leads I and aVL would predict a left atrial location.

JUNCTIONAL ECTOPIC TACHYCARDIA

The mechanism of JET is believed to involve a small focus within the AV node or bundle of His exhibiting abnormal automaticity. As with AET, these rhythms are often incessant, and although they might be well tolerated hemodynamically in the short term, they can lead to cardiomyopathy if not well controlled. They can also manifest in the newborn infant as nonimmune hydrops fetalis. The congenital form of JET had a high mortality rate in the era before the availability of catheter ablation.[7,19,20]

The classic electrocardiographic appearance of JET is a narrow QRS tachycardia with AV dissociation and capture beats (Fig. 45-24). The ventricular rate is faster than the atrial rate, often as fast as 300 beats per minute. AV dissociation is due to lack of retrograde conduction from the junctional focus back to the atrium. Capture beats are caused by

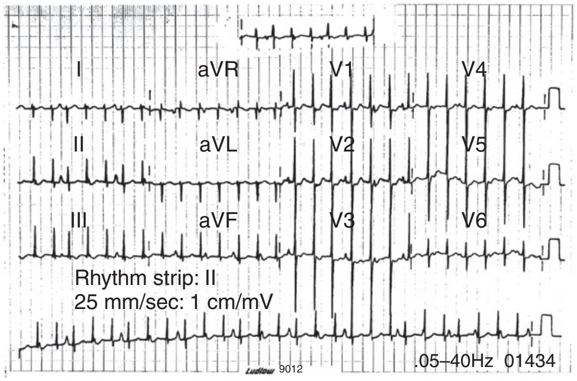

Figure 45–24. Twelve-lead electrocardiogram of infant with congenital junctional ectopic tachycardia. Note easily seen atrioventricular dissociation. *(From Van Hare GF, et al: Successful transcatheter ablation of congenital junctional ectopic tachycardia in a ten-month-old infant using radiofrequency energy,* Pacing Clin Electrophysiol *13:730, 1990.)*

dissociated sinus beats that periodically occur at a time when anterograde AV nodal conduction is possible. The R-R interval shortens suddenly, and the QRS complex of the capture beat is no narrower than the QRS complex during tachycardia.

Occasionally, JET can be seen in which retrograde conduction is intact. In such patients, there are no AV dissociation or capture beats, which makes the diagnosis more challenging. Burst esophageal pacing or adenosine infusion can be used to produce brief episodes of AV block, facilitating the diagnosis.

VENTRICULAR TACHYCARDIA

Neonates with idiopathic incessant or paroxysmal ventricular tachycardia typically have structurally normal hearts. Infants with incessant tachycardia and rapid rates have signs of congestive heart failure at presentation. The paroxysmal form of ventricular tachycardia seen in neonates is usually better described as ventricular accelerated rhythm because the rates are only slightly faster than sinus rhythm. This rhythm usually resolves spontaneously within several months or years.[18] Infants with the long QT syndrome occasionally have episodes of torsades de pointes in the newborn period (Fig. 45-25).

Ventricular tachycardia is recognized from wide QRS complexes, AV dissociation, and capture beats (Fig. 45-26). Unlike JET, in which the capture beats are no narrower than the tachycardia beats, in ventricular tachycardia the capture beats should be narrower than the tachycardia beats, often with a normal QRS duration and morphologic picture. The reason is that the capture beat is a random sinus beat that finds the AV conducting system no longer refractory. It conducts down the conducting system normally, narrowing the QRS. In infants, however, AV dissociation might not be seen because ventriculoatrial conduction is often present. Moreover, because sustained bundle branch aberration is rarely seen in infants with supraventricular tachycardia, many or most wide QRS tachycardias that one encounters in this age group are due to ventricular tachycardia.

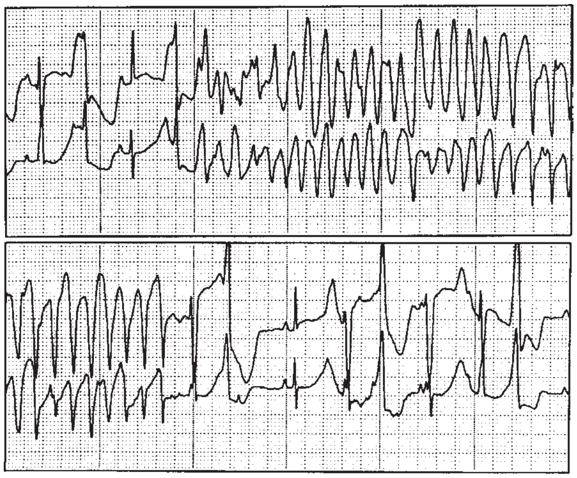

Figure 45–25. Torsades de pointes in infant with long QT syndrome who had an irregular heart rate in the delivery room. *(From Van Hare GF, et al: Successful transcatheter ablation of congenital junctional ectopic tachycardia in a ten-month-old infant using radiofrequency energy,* Pacing Clin Electrophysiol *13:730, 1990.)*

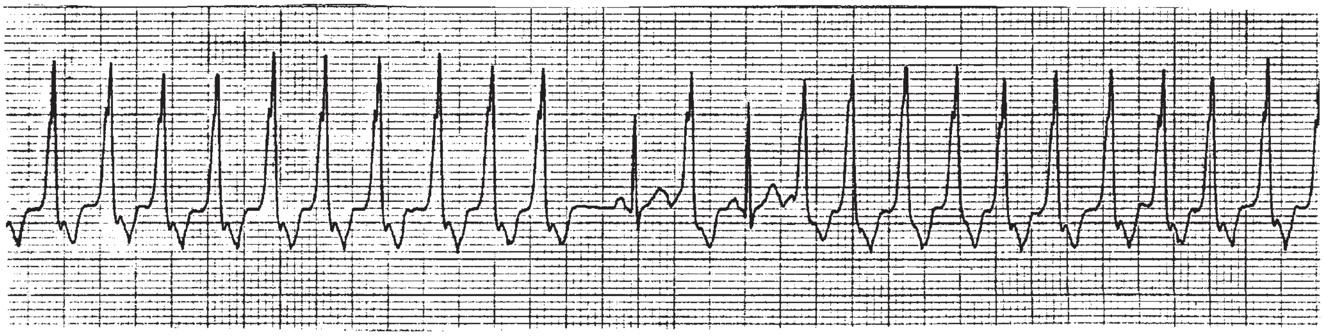

Figure 45–26. Ventricular tachycardia at rate of 230 beats/min in an infant. Note sudden termination, followed by sinus beat, followed by immediate reinitiation.

MECHANISMS OF BRADYCARDIA

Specific Mechanisms

SINUS BRADYCARDIA

Newborn infants are thought to have incomplete sympathetic cardiac innervation and are predominantly vagally innervated. As a result of this autonomic imbalance, episodic sinus bradycardia is fairly common. Sinus bradycardia is recognized as a regular slow atrial rate with normal P waves and 1:1 conduction. Pathologic causes of sinus bradycardia include hypoxia, acidosis, increased intracranial pressure, abdominal distention, and hypoglycemia. Drugs such as digoxin and propranolol can also cause significant sinus bradycardia. Episodic bradycardia often accompanies apnea of prematurity (see also Chapter 44).

SECOND-DEGREE ATRIOVENTRICULAR BLOCK

Second-degree AV block is classified as either Mobitz type 1 (Wenckebach) or Mobitz type 2. Wenckebach conduction is characterized by progressive prolongation of the PR interval, which eventually results in a single blocked atrial beat. Wenckebach conduction is caused by block in the AV node, and it can usually be reversed with catecholamines or with vagolytic agents. Type 2 block lacks the characteristic progressive PR prolongation with shortening after the blocked beat seen in Wenckebach conduction. It is usually not reversible with medication. Type 1 second-degree AV block generally has a better prognosis than type 2. One specific form of second-degree block requires immediate attention: the form of 2:1 conduction seen in infants with markedly prolonged QR intervals. Two-to-one conduction in such infants is an important risk factor for the development of torsades de pointes and sudden death.

COMPLETE ATRIOVENTRICULAR BLOCK

Complete AV block can be congenital, surgically induced, or acquired, for example, after myocarditis. It is due to complete block of conduction either in the AV node or in the distal (His-Purkinje) system. It is recognized as AV dissociation with regular R-R intervals and regular P-P intervals. The atrial rate is usually greater than the ventricular rate, and P waves that occur well after the T wave have no effect on the R-R interval. Congenital AV block can be associated with maternal lupus (see Part 2 of this chapter and Chapter 18), ventricular inversion, and mutations in the *NKX2.5* gene.[5]

Miscellaneous Causes

Other causes of bradycardia are sinus exit block, in which sinus P waves intermittently disappear because impulses leaving the region of the node are blocked, and frequent premature atrial contractions, which occur too early to be conducted to the ventricles and therefore slow the resulting ventricular rate.

CAUSES OF PREMATURE BEATS

The new onset of frequent premature beats often is the clue to underlying conditions such as toxic effects of digoxin or other drugs, myocarditis, hypoxia, hypokalemia, hypercapnia, or acidosis.

Supraventricular Premature Contractions

Supraventricular premature contractions are caused by a focus in the right atrium, left atrium, or proximal AV node that depolarizes before the sinus node. Those that originate in the atrium produce a premature P wave that is superimposed on and deforms the previous T wave. This sign can be subtle, however, and requires examination of multiple leads. The premature P wave is followed by a premature narrow QRS beat. Supraventricular premature contractions can also have wide QRS complexes because of a bundle branch aberration. In these babies, the observation of a preceding premature P wave is essential for differentiating an aberrant beat from a ventricular premature contraction. Premature atrial contractions are fairly common in newborn infants and are benign in the absence of structural cardiac disease or other illnesses.

Ventricular Premature Contractions

Ventricular premature contractions occur from a ventricular focus that depolarizes before the atrial beat is conducted through the AV node. They are wide premature beats without a preceding early P wave. Differentiating between ventricular contractions and aberrantly conducted supraventricular contractions is sometimes difficult or impossible from the surface electrocardiogram. Although, traditionally, premature ventricular beats can be differentiated from supraventricular beats by the presence of a full compensatory pause, this sign is somewhat unreliable in children. Fusion beats, in which a sinus beat occurs simultaneously with a premature beat, thus creating an intermediate morphologic picture, help to establish the premature beat as ventricular in origin. When premature ventricular beats are identified in a newborn infant, a careful search for structural or functional cardiac disease is required, together with an evaluation to rule out electrolyte disorders.

INITIAL MANAGEMENT OF TACHYCARDIA

Severity Assessment

When an infant is first found to have a cardiac arrhythmia, the physician should immediately make an assessment of the hemodynamic condition. Some arrhythmias require emergency therapy (electrical cardioversion, pacing), whereas others are less urgent and allow more time for evaluation and electrocardiographic analysis before therapy is instituted. Infants can be free of symptoms, can have mild symptoms, or can be seriously ill or critically ill at first identification.

SYMPTOM-FREE OR MILDLY AFFECTED INFANTS

It is not unusual for infants with moderate or short episodes of tachycardia to be completely free of symptoms during the arrhythmia. These cases are detected on routine examination or are noticed by nurses or parents. The decision to treat the child depends on the presence of structural heart disease, Wolff-Parkinson-White syndrome, and other factors. Some symptom-free neonates do not require short- or long-term treatment. In other cases, episodes are notable by a change in activity on the part of the infant when no respiratory distress or other signs of compromise are present. In these cases or when there is an increased risk for prolonged arrhythmia, long-term treatment is necessary (Tables 45-10 and 45-11).

SERIOUSLY ILL INFANTS

When major symptoms develop in a neonate, emergency treatment is required. The time required to develop congestive heart failure varies according to age, heart rate, and the presence or absence of structural heart disease. Newborn infants can tolerate rates of 300 beats per minute and higher for many hours before signs of congestive heart failure develop. In children with structural heart disease, particularly with significant cyanosis, chronic congestive heart failure, or significant valvular obstruction, tachycardia is usually poorly tolerated.

The seriously ill infant might be fretful and irritable, sweaty, pale, and tachypneic and could be feeding poorly. The liver might be enlarged, with a prominent left lobe. Infants rarely manifest pulmonary edema with rales on auscultation of the chest but might have wheezing and appear to be having primarily a pulmonary problem. Cardiac auscultation might reveal an abnormally fast heart rate, often with a gallop rhythm.

Further evaluation should include questioning of the parents for a history of heart disease, arrhythmias, antiarrhythmic or other medications, and allergies to medications. A chest radiograph might reveal cardiomegaly, and pulmonary venous congestion.

CRITICALLY ILL INFANTS

Heart rates sufficiently fast or slow can result in critically low blood pressure, nonpalpable pulses, altered sensorium, complete loss of consciousness. Although seriously ill patients are generally stable enough to tolerate a small delay of therapy for gathering information, placing intravenous lines, measuring arterial blood gas tensions, obtaining a complete electrocardiogram, and attempting nonpharmacologic maneuvers, critically ill patients require definitive treatment within 2 or 3 minutes of the onset of the arrhythmia. If there will be any delay before electrical cardioversion or the institution of pacing, cardiopulmonary resuscitation or mechanical support required to support the circulation.

Rapid Classification of Abnormal Tachycardia

After assessing the hemodynamic status of the neonate with tachycardia, the rhythm is classified as either a wide or narrow QRS tachycardia. A narrow QRS tachycardia has a QRS duration similar to that during normal sinus rhythm or is in the normal range for age. The QRS duration in wide-complex tachycardia is significantly longer than the duration in normal sinus rhythm, or longer than the 95th percentile for age. Nearly all narrow QRS tachycardias in infants are supraventricular in origin, and most wide QRS tachycardias are ventricular in origin.

Any form of narrow QRS tachycardia could manifest *aberration*, defined as widening of the QRS complex. Aberration is usually due to rate-dependent bundle branch block. The onset of aberration can be progressive, and once established, aberration can persist until termination. Because widening of the QRS complex results from rate-dependent bundle branch block, it usually resembles a right or left pattern of bundle branch block.

Aberration with supraventricular tachycardia often occurs at the onset of the tachycardia in the absence of preexisting bundle branch block, but sustained bundle branch aberration

TABLE 45–10 Intravenous Antiarrhythmic Agents

Agent	Dosage	Comments
Esmolol	50-500 micrograms/kg/min	Monitor pulse, blood pressure Contraindicated in congestive heart failure Do not give with verapamil
Procainamide	10-15 mg/kg IV over 30-45 min	Can cause hypotension Continuous blood pressure monitoring is essential
Digoxin	10 micrograms/kg IV as initial load; second dose in 6 hr and third at 24 hr	Do not use in hypokalemia or if toxic reaction to digoxin is suspected
Lidocaine	1-2 mg/kg IV over 15 min; continuous infusion of 30-50 micrograms/kg/min	
Phenylephrine	20 micrograms/kg IV slowly	Used for raising blood pressure and eliciting a baroreceptor vagal reflex
Adenosine	Start IV dose of 100 micrograms/kg; double dose repeatedly until effect is seen, to maximum of 400 micrograms/kg	Contraindicated in preexisting second- and third-degree AV block without pacemaker Use with caution in severe asthma; half-life is 10 sec in serum Occasionally induces atrial fibrillation
Amiodarone	5 mg/kg IV over 15-30 min or as 5 separate 1 mg/kg aliquots	Given by central line diluted in D_5W Can cause gasping syndrome in infants due to benzyl alcohol Continuous infusion probably should not be used in infants

IV, intravenously.

TABLE 45–11 Oral Antiarrhythmic Agents

Agent	Dosage	Comments
Propranolol	0.25-1 mg/kg PO every 6 hr	Observe for wheezing and symptoms of hypoglycemia
Atenolol	0.5-2 mg/kg/day PO divided every 12 hr	
Procainamide	50-100 mg/kg/day PO divided every 8 hr	Monitor both procainamide and NAPA levels
Quinidine sulfate	30-60 mg/kg/day PO divided every 6 hr	
Flecainide	50-200 mg/m^2/day PO divided every 12 hr or 6.7-9.5 mg/kg/day divided every 8 hr	Flecainide levels $>$1.0 micrograms/mL correlate with toxic effects
Mexiletine	1.4-5.1 mg/kg PO every 8 hr	
Digoxin	10 micrograms/kg PO as initial load Second dose in 6 hr, third in 24 hr; reduce dosage in premature infants	Do not use in hypokalemia or if digoxin toxic reaction is suspected
Amiodarone	5 mg/kg PO bid × 2 wk, then 2.5 mg/kg PO bid	Monitor thyroid and pulmonary function
Sotalol	2-8 mg/kg/day PO divided every 8 hr	Torsades de pointes is likely with hypokalemia

bid, twice a day; NAPA, *N*-acetylprocainamide; PO, orally.

with supraventricular tachycardia is rare in infants. Therefore, most wide QRS tachycardias in infants are due to ventricular tachycardia.

Therapeutic Options

The therapeutic options are listed in Box 45-14.

General Acute Therapeutic Approach

NARROW QRS TACHYCARDIA

For critically ill infants with any form of narrow QRS tachycardia, synchronized electrical cardioversion is indicated. For seriously ill infants, in whom there can be signs of congestive heart failure but who have a measurable blood pressure and are conscious, the clinician must judge the stability of the patient's hemodynamic status. If the status is unstable, the patient should have electrical cardioversion after placement of an intravenous line. More stable patients are managed by means of vagal maneuvers followed by adenosine, with electrical cardioversion as an option if these measures fail (Box 45-15).

WIDE QRS TACHYCARDIA

Most infants with wide QRS tachycardia have ventricular tachycardia rather than supraventricular tachycardia with an aberration. Because it may be nearly impossible to differentiate these possibilities in neonates with only a surface electrocardiogram, patients with wide QRS tachycardia are treated as if they have ventricular tachycardia. In practice, this means that electrical cardioversion is indicated in most cases.

In patients who are not seriously or critically ill, one can defer cardioversion while pharmacologic agents are administered. In this situation, procainamide would be a good choice because it is effective both for ventricular and supraventricular arrhythmias. Lidocaine can be used if the diagnosis of ventricular tachycardia is certain.

For infants with few or no symptoms, beta blockers such as propranolol are often effective. Propranolol should be used with great care; however, if tachycardia is not controlled by propranolol, the hypotension and poor cardiac contractility that can be produced by propranolol will be poorly tolerated in the presence of continuing tachycardia.

Infants in whom the long QT syndrome with polymorphous ventricular tachycardia (torsades de pointes) is suspected should not receive procainamide or lidocaine. They should instead receive propranolol, possibly intravenously, with the possible addition of temporary ventricular pacing, particularly if they also manifest episodes of second-degree AV block.

Therapy for Specific Tachyarrhythmias

ATRIAL FLUTTER

Therapy can be directed toward converting the tachycardia to sinus rhythm or toward limiting the ventricular response. Vagal maneuvers can be successful in converting the rhythm but can also be useful diagnostically by causing a short episode of AV block without terminating the tachycardia and revealing the underlying flutter waves. Digoxin, propranolol, or esmolol can be used to slow the ventricular response and can also assist in converting the tachycardia.

Procainamide can be effective in converting the tachycardia, but there is a chance of slowing the atrial rate without converting the rhythm. If the faster atrial rate was associated with variable AV conduction, the slower rate can allow 1:1 AV conduction, paradoxically increasing the ventricular rate. For this reason, procainamide should be used only after a drug that limits AV conduction, such as digoxin, is given.

If tachycardia conversion is necessary immediately, the first choice is esophageal atrial overdrive pacing. This method is effective, particularly in small children, and does not require anesthesia. In postoperative cardiac surgery patients,

BOX 45–14 Therapeutic Options for Tachycardia

VAGAL MANEUVERS

Use with IV line in place; do not continue for more than 5 minutes in seriously ill infants before trying other modalities.

Elicit gag with nasogastric tube.

Elicit diving reflex by placing a bag filled with ice over the face and ears for 15 seconds.

Do not perform carotid massage or apply orbital pressure.

ADENOSINE

Used for supraventricular tachycardias that involve the AV node as part of reentrant circuit.[14]

Give by rapid IV injection; onset of effect seen in 7 or 8 seconds, half-life in blood is less than 10 seconds; AV blockade is brief. Do not give by umbilical artery.

If conversion is successful, provides evidence against other forms of tachycardia.

Transient AV block can reveal flutter waves in atrial flutter, so diagnosis can be made.

Caution: Adenosine is a negative inotrope, but this factor is rarely a problem.

DIGOXIN

Effective for most neonatal narrow QRS tachycardias.

Disadvantage is a relatively long period needed to achieve therapeutic drug levels safely.

Do not give if baby has hypokalemia or if toxic reaction to digoxin is suspected.

Give with care if renal failure is suspected (excretion of digoxin entirely renal); acts by slowing sinus node, lengthening PR interval.

Only antiarrhythmic drug that improves contractility.

CLASS I AGENTS (SODIUM CHANNEL BLOCKERS)

Procainamide

Effective in atrial arrhythmias and in some AV reciprocating tachycardias or AV node reentrant tachycardias.

Give IV or PO; hypotension is common with loading dose.

Drug levels correlate with efficacy.

Measure both procainamide and *N*-acetylprocainamide.

Can cause negative inotropic effects and lupus-like syndrome.

Quinidine

Similar electrophysiologic effect to procainamide, less effect on contractility.

Do not give intravenously; diarrhea is most common side effect in infants.

Quinidine and Procainamide

In atrial flutter, fibrillation, or atrial ectopic tachycardia, both agents slow atrial rate but shorten AV node refractory period, increasing ventricular rate by decreasing block at AV node.

Best to give digoxin or propranolol before procainamide or quinidine therapy in such patients.

Both prolong QT interval and should not be given to infants with long QT syndrome.

Effect is additive with several drugs, including erythromycin.

Other signs of toxic effects with both are prolongation of PR interval and QRS duration.

Mexiletine and Lidocaine

Both drugs shorten QT interval but have no effect on sinus rates and conduction.

Mexiletine is given PO and lidocaine is given IV.

Flecainide

Limited use in children because adult trials showed excessive mortality rate when used for ventricular arrhythmias.

Not considered arrhythmogenic in children with structurally normal hearts; has been used to treat atrial arrhythmias.[10]

Drug is a negative inotrope; slows sinus node and prolongs PR interval.

Propafenone

Used for junctional ectopic tachycardia and other refractory atrial tachycardias.[13]

Shares similar hemodynamic and electrophysiologic characteristics with other type I agents but tends to slow sinus rate.

CLASS II AGENTS (BETA BLOCKERS)

Propranolol

Limited side effects; decreased contractility, hypoglycemia, asthma, and fatigue seen in older children.

Atenolol

Little experience in very young children. Might have fewer central nervous system side effects than propranolol.

Half-life longer than propranolol in adults, shorter in young children; twice-daily dosing could be required.

Both Agents

Negative inotropes; slow sinus node and prolonged PR interval.

CLASS III AGENTS (POTASSIUM CHANNEL BLOCKERS)

Sotalol

Has both class III and beta-blocking properties.

Given orally.

Effective in atrial arrhythmias in children.[3,16]

Amiodarone

Long used in Europe.[6]

Used in refractory atrial arrhythmias.

IV loading followed by oral administration overcomes long time required for oral loading.

If used IV, has additional beta-blocking and calcium channel blocking properties.

Sotalol and Amiodarone

Increase PR interval and QRS duration and slow sinus node.

CLASS IV AGENTS (CALCIUM CHANNEL BLOCKERS)

Verapamil

IV form never given to infants (causes hypotension and asystolic cardiac arrests in those <6 months of age).

Oral form is used in atrial flutter.

Has negative inotropic effects, slows sinus nodes, and prolongs PR interval.

ESOPHAGEAL AND TRANSVENOUS ATRIAL PACING

Works well in neonatal period.[4]

Brief atrial overdrive pacing at rate higher than tachycardia might allow termination of atrial tachycardias, including atrial flutter.

BOX 45–14 Therapeutic Options for Tachycardia—cont'd

Transvenous

Place sheath in large vein (femoral, internal jugular, or subclavian) and direct bipolar pacing catheter to right atrium or right ventricle.

Esophageal

Position esophageal lead behind left atrium for pacing; use pulse generators that generate long pulse widths (at lest 10 msec) because outputs required for capture at conventional pulse widths (>2 msec) are very uncomfortable for the infant.

Using Fluoroscopy

With pacing leads connected to external pulse generator, select rate, turn on generator, and increase output until capture is achieved.

ELECTRICAL CARDIOVERSION

Used rarely in newborn infants.

Cardioverter-defibrillator must deliver very low amplitude shocks and have small paddles (those used for direct delivery to epicardial surface of heart in older patients intraoperatively are appropriate).

Initial dose is 0.5-1.0 J/kg.

Converts narrow QRS tachycardias in synchronous mode to avoid delivery on T wave.

Perform defibrillation for ventricular fibrillation in asynchronous mode.

With wide QRS tachycardias in synchronous mode to avoid delivery on T wave.

Perform defibrillation for ventricular fibrillation in asynchronous mode.

With wide QRS tachycardias, initially use synchronous mode; some forms of ventricular tachycardia appear almost sinusoidal, and cardioverter-defibrillator might not sense R wave well. Therefore, use of asynchronous mode might be needed.

No specific precautions are needed with therapeutic doses of digoxin, but with high levels of toxic reaction to digoxin, give initial bolus of lidocaine, 1 mg/kg IV, before cardioversion.

TRANSCATHETER ABLATION

Treatment of choice for many atrial tachycardias in children and adults with symptoms.

In very young children, concerns involve depth of scar, growth of scar over time, and risk for injury to adjacent structures (see discussion of accessory pathway reentrant tachycardia).

BOX 45–15 Treatment of Supraventricular Tachycardia

ACUTE CONDITIONS

Critically Ill Infants

Synchronized cardioversion, 0.5 J/kg

All Others

Electrocardiographic monitoring and IV access

Vagal maneuvers

Nasogastric stimulation

Ice to face for 30 sec

Adenosine, 100 micrograms/kg, given by rapid IV infusion (not in umbilical artery)

Repeat 200 micrograms/kg and then give 400 micrograms/kg if no effect

Esophageal pacing, atrial pacing, or cardioversion

CHRONIC CONDITION

For infants with Wolff-Parkinson-White syndrome or if status is unknown: propranolol, 0.5 mg/kg PO every 6 hr

For infants with no documented accessory pathway: digoxin, 5 micrograms/kg PO every 12 hr after initial load

---

IV, intravenous; PO, orally.

temporary atrial pacing wires can be used. If this method fails or is not available, electrical cardioversion with deep sedation or anesthesia will be effective.

For long-term treatment, the first choice is digoxin or propranolol orally. If therapy with one of these drugs fails, one can add sotalol, given three times a day.[3,16] Other choices include flecainide, given two or three times a day,[10] or propafenone, given three times a day.[13]

When atrial flutter occurs in the newborn period, it often disappears within the first 6 months of life.[4] Although traditionally such infants have been treated for 1 year with digoxin, there is evidence that they can be successfully followed without medication after initial conversion.

ATRIOVENTRICULAR NODE REENTRANT TACHYCARDIA

Short-term treatment of AVNRT is directed at achieving a brief episode of AV block. Neonates might respond to vagal maneuvers or rectal stimulation. If vagal measures fail, our first choice of medication is intravenously administered adenosine. Intravenous administration of esmolol or digoxin might also be effective. Esophageal or intracardiac atrial overdrive pacing is effective. Neonates with refractory AVNRT also respond to electrical synchronous cardioversion.

Long-term management is directed at changing conduction through the slow AV nodal pathway. Oral digoxin or propranolol might be effective. AV node modification with radiofrequency energy or by cryoablation is possible but is rarely employed in the neonate.

The natural history of this condition in infants is unknown, but the condition may well disappear with time. Therefore, it is reasonable to treat such infants with antiarrhythmic medications for several years with the hope of avoiding transcatheter ablation.

ACCESSORY PATHWAY REENTRANT TACHYCARDIA

As in AVNRT, acute treatment can be directed at either the antegrade AV node conduction or the retrograde accessory pathway conduction. Vagal maneuvers or drugs such as adenosine,[14] digoxin, or propranolol can be used to affect the antegrade limb of the reentrant circuit. The retrograde accessory pathway conduction can be affected by procainamide or flecainide.[10] Esophageal pacing is effective in terminating an episode, either by atrial overdrive or extrastimulation, and is the second choice when available and when vagal maneuvers fail. Electrical cardioversion is also effective.

Long-term management depends on the severity of the problem and the frequency of the attacks. For infants with rare, mildly symptomatic attacks of supraventricular tachycardia that are easily terminated, we advise no treatment at all. Infants with more frequent or symptomatic attacks are treated initially with beta blockers. Digoxin is used only if there is no evidence of pre-excitation in sinus rhythm. About one third of adults with pre-excitation treated with digoxin have a shortening of the anterograde ERP of the accessory pathway, which could be dangerous if atrial fibrillation develops. Although atrial fibrillation is uncommon in infants and digoxin has been used for years in the treatment of children with pre-excitation, with few if any documented problems, some reports suggest the possibility of sudden death in infants treated with digoxin.[8]

Transcatheter ablation of the accessory pathway is increasingly being used as first-line therapy in children, but its use in infants is still limited.[11] The reason is the concern of complications such as perforation, AV block, and damage or occlusion of major coronary arteries. In addition, the natural history of accessory pathway tachycardia in infancy is favorable: 75% to 90% of such infants have spontaneous resolution of tachycardia by 12 months of age.[15] Ablation is reserved for life-threatening, medically refractory cases.[1] Often, the patients have PJRT and dramatically compromised left ventricular function.

PERMANENT FORM OF JUNCTIONAL RECIPROCATING TACHYCARDIA

Treatment of children with PJRT is often challenging. In addition to the techniques and drugs used for infants with Wolff-Parkinson-White syndrome, amiodarone is often effective, and spontaneous resolution is occasionally observed.[17]

ATRIAL ECTOPIC TACHYCARDIA

Treatment of AET is difficult, and rate control might be the only achievable therapy. The atrial focus could be slowed by beta blockers, flecainide, or propafenone or by class III agents such as sotalol and amiodarone. The goal of treatment is to protect the patient from the subsequent development of tachycardia-induced cardiomyopathy. Definitive intervention for cure of tachycardia, either by radiofrequency ablation or cryoablation or by surgical cryoablation, should be done at the earliest signs of poor cardiac function shown by echocardiography.[21]

JUNCTIONAL ECTOPIC TACHYCARDIA

The pharmacologic approach to AET can also be effective in the treatment of JET. Although no agent is reliably effective in treating this arrhythmia, amiodarone is often effective. In selected patients, transcatheter ablation has been employed to eliminate the junctional focus. In very small infants, because of the proximity of the JET focus to the AV node, there is a risk for causing complete AV block at the time of the ablation, although this risk is likely to be lower with cryoablation. The potential for permanent pacemaker implantation limits the applicability of this technique to the sickest infants who have not responded to all classes of antiarrhythmic agents.[7,19]

Postoperative JET is usually seen in babies with low cardiac output. In this situation, JET could be caused by the poor cardiac output or could be contributing to the hemodynamic compromise. Intravenous amiodarone is widely used in this setting.[6] Surface cooling can slow the junctional rate and allow effective AV sequential pacing. This restores AV synchrony, which often improves the cardiac output.[2] Unlike congenital JET, postoperative JET is transient and resolves as the myocardium recovers.[22]

VENTRICULAR TACHYCARDIA

Pharmacologic suppression of ventricular tachycardia, when it is dependent on catechol stimulation for induction, usually includes the use of moderate to high doses of beta-blocking medications. When the use of esmolol, propranolol, or atenolol is not successful, or when the rhythm is not dependent on catecholamines, class I agents such as mexiletine and flecainide can be used. Class III agents such as sotalol and amiodarone might also be effective. Infants with ventricular accelerated rhythm, however, probably do not require any treatment because the tachycardia rate is not fast enough to produce hemodynamic compromise and because these rhythms usually resolve by several months of age.[18]

TREATMENT OF BRADYARRHYTHMIAS

The hemodynamic effect of a slow heart rate depends on the actual rate and the degree of difference from the baby's usual heart rate. Sudden decreases in rate can be poorly compensated by increases in stroke volume, particularly in neonates with preexisting poor cardiac function. Bradycardia caused by sinus slowing can be induced by hypoxia, vagal stimulation during nasogastric tube placement, or gastroesophageal reflux. Blocked premature atrial beats, when they occur in a bigeminal pattern, cause sustained bradycardia.

Despite episodic rates of 70 beats per minute, this rhythm rarely requires treatment in otherwise normal babies. Congenital complete AV block could require treatment if there is coexisting heart disease or particularly slow ventricular escape rates. Postoperative complete AV block is treated in the acute stage by temporary pacing and, if it persists, by permanent pacing.

If treatment is indicated, initial treatment with atropine, followed by continuous isoproterenol infusion, increases sinus rates, improves AV conduction, and can increase the rate of subsidiary pacemakers. After initial stabilization with medications, temporary transvenous pacing should be instituted, particularly in cases with very low ventricular rates (less than 45 beats per minute in the neonate) and those with hemodynamic compromise. Subsequently, implantation of a permanent pacemaker might be necessary if bradycardia does not improve.

TREATMENT OF PREMATURE BEATS

In the absence of tachycardia, neonates only rarely need treatment for premature beats of any kind. Supraventricular premature contractions virtually never require treatment. Ventricular premature contractions could require treatment in the following situations:

- When they are multiform
- When they occur in couplets or short runs of ventricular tachycardia
- When they are seen in association with a recently converted ventricular tachycardia
- When they exhibit the "R on T" phenomenon (i.e., they fall repeatedly on the early part of the T wave of the preceding beat)

Decisions concerning treatment of premature beats are difficult and should be made in consultation with a cardiologist. As usual, possible inciting factors such as hypoxia and acidosis should be corrected. If ventricular premature contractions require emergency treatment, the agents of choice are lidocaine or amiodarone, given as a bolus followed by a continuous intravenous infusion.

PART 10

Principles of Medical and Surgical Management

Kenneth G. Zahka and Ernest S. Siwik

GENERAL PRINCIPLES

General principles that apply to the care of critically ill neonates are the basis of medical care of the baby with congenital heart disease. Thermal regulation, nutritional and metabolic derangements, identification and treatment of infections, and the techniques of ventilatory support are discussed in other chapters in detail.

For the baby with congenital heart disease, it is essential that the clinician understand the anatomy, pathophysiology, and natural history of the defect. This guides the decision to start medical or surgical therapy. One goal of therapy may be to modify the anatomy with prostaglandin E_1, interventional catheterization, or surgery. Another goal may be to alter the physiology through changes in heart rate, preload, afterload, or contractility.[3]

After neonatal surgery, a precise knowledge of the type of surgery and the expected changes in the circulation can help predict the baby's needs. Careful serial physical examination and review of available physiologic data make management of the postoperative patient not only safer and effective but also more gratifying. Anticipating problems by evaluating trends in systemic and pulmonary arterial blood pressure, atrial pressures, heart rate, and systemic venous oxygen saturation[60] and thus initiating therapy can improve outcomes. Intraoperative and postoperative echocardiography has greatly added to our ability to assess residual defects and ventricular function. If these data do not answer the question of why a baby is struggling after surgery, cardiac catheterization must be performed with the goal of identifying residual defects or problems that might be amenable to medical therapy or surgery.

Oxygen and Ventilation

Experience with the preoperative and postoperative management of infants with hypoplastic left heart syndrome has raised the awareness of the unique pathophysiology of the child with potentially limited systemic blood flow and exuberant pulmonary blood flow.[66] Preoperatively, the ductus arteriosus is large, and balancing the systemic and pulmonary blood flow requires attention to both the systemic vascular and pulmonary vascular resistance.[5] Therapies that decrease total pulmonary resistance or increase systemic resistance direct an excessive amount of flow to the lungs and steal flow from the systemic circulation. This results in poor systemic perfusion despite a widely patent ductus arteriosus. This is especially deleterious in babies with impaired ventricular function or tricuspid regurgitation. Conversely, pulmonary vasoconstriction or systemic vasodilation limits pulmonary blood flow and increases systemic blood flow. This results in lower systemic arterial oxygen saturation, which, if severe, can compromise tissue oxygen delivery despite good blood flow. In this setting, a highly restrictive atrial septal defect further reduces pulmonary blood flow and limits systemic oxygen delivery.

Babies at risk for excessive pulmonary flow or decreased systemic flow can usually breathe room air unless severe pulmonary edema causes pulmonary venous desaturation. Similarly, hyperventilation with the resultant hypocapnia and alkalosis lowers the pulmonary vascular resistance. Unless there is poor respiratory effort or concern about apneic episodes related to prostaglandin E_1, spontaneous breathing offers the advantage of allowing the infant to achieve normal ventilation. If the infant has undergone intubation and is sedated, the minute ventilation should be adjusted to achieve normal arterial carbon dioxide tension ($PaCO_2$) and pH. In babies with hypoplastic left heart syndrome, atrial septostomy is usually avoided unless the atrial opening is critically small. A modest degree of left atrial hypertension adds to the total pulmonary resistance and limits pulmonary blood flow. There are babies with hypoplastic left heart syndrome for whom this conservative approach is inadequate, and they develop signs of systemic hypoperfusion. In these babies, hypoventilation using mechanical ventilation and muscle relaxants and subambient oxygen levels[66] are important techniques for avoiding hemodynamic instability.

Babies with restricted pulmonary blood flow can be treated with supplemental oxygen without risk but with the recognition that there might be little increment in the arterial oxygen saturation. If there is clinical or echocardiographic evidence that pulmonary hypertension with high pulmonary vascular resistance is causing the reduced pulmonary flow and hypoxia, supplemental oxygen is essential. Further approaches to modulating the pulmonary vascular resistance are discussed in Part 8 under "Persistent Pulmonary Hypertension (Persistent Fetal Circulation)."

Postoperatively, the restriction to pulmonary blood flow provided by a systemic-pulmonary shunt or right ventricle-to-pulmonary artery conduit permits a greater focus on optimizing systemic oxygen delivery through reduction of systemic vascular resistance.[42] Systemic vascular resistance can be modulated by the addition of milrinone or a specific systemic vasodilator such as nitroprusside or phenoxybenzamine. Increasing arterial CO_2 either through permissive hypoventilation or the addition of carbon dioxide to the ventilator circuit drops cerebral vascular resistance and improves oxygen delivery, as evidenced by increased systemic venous saturation, and simultaneously reduces oxygen consumption.[42] Splanchnic blood flow, however, is reduced by this strategy, raising concern that in some neonates there is an increased risk for intestinal ischemia.

Blood

Oxygen delivery to the tissues is dependent on adequate hemoglobin concentration. Anemia causes a higher cardiac output to maintain oxygen delivery. If the infant is unable to produce an increased cardiac output, increased oxygen extraction leads to lower systemic venous oxygen saturation. For the neonate with a normal arterial oxygen saturation and adequate cardiac output, mild anemia is well tolerated. For the baby with severe hypoxia or poor cardiac output, anemia impairs oxygen delivery because increased extraction might not be possible or because it taxes the fragile cardiovascular reserve.

With recognition of the risks of blood transfusion, it is prudent to use all means to minimize blood loss and maximize erythropoiesis. Transfusion to maintain a hematocrit of at least 40% for babies with significant cyanosis or with impaired cardiac output should be considered when clinical symptoms are evident. The clinician might need to take special precautions to avoid volume overload in babies with congestive heart failure, prolonging either the transfusion or giving concomitant diuretics. Radiation of the blood is essential for any baby in whom the DiGeorge syndrome is suspected.

Prostaglandin E_1

Neonates who are expected to fit one of the categories in which ductal dependence is likely or who are known from fetal studies to be ductal dependent should begin prostaglandin E_1 therapy immediately.[23] In general, the more severe the cyanosis or the systemic hypoperfusion, the more urgent the administration of prostaglandin E_1. If there is some doubt about the proper category and the infant is ill with respiratory distress, it is reasonable to begin treatment with prostaglandin E_1 while further evaluation is undertaken.

The response of the ductus arteriosus to prostaglandin E_1 is related to the time since spontaneous closure. Cyanosis in newborn infants is usually recognized shortly after ductal closure; therefore, the infants respond well to prostaglandin E_1. Babies with cyanosis beginning at several weeks of age should not be assumed to be unresponsive to prostaglandin E_1. It is possible that the ductus arteriosus had recently closed, and thus it may well respond to prostaglandin E_1.

Babies with coarctation of the aorta might be able to survive for several days with marginal blood flow through the obstruction before they are recognized to be in trouble. Although they might respond to prostaglandin E_1, they have the highest likelihood of not responding and of needing urgent surgery.

Prostaglandin E_1 is administered intravenously through a peripheral vein or central venous catheter. The initial studies also include umbilical artery administration with no apparent adverse effects.[23] The initial dose is 0.05 μg/kg per minute, and this can be decreased to 0.03 μg/kg per minute once an effect is seen. The principal side effect of short-term administration of prostaglandin E_1 is apnea, which is most frequent in premature infants and at the higher doses but can occur in full-term infants. Apnea can occur several hours after the start of prostaglandin E_1 administration. Doses as low as 0.01 μg/kg per minute can be effective and tend to decrease the risk of apnea.[38] Depending on the type of transport, elective intubation before transport might be advisable. Other dose-dependent, short-term side effects include skin flushing and fever.

Long-term administration of prostaglandin E_1 could be required for the neonate with other medical problems or for the premature baby. Oral administration of prostaglandin E_2 has been used with some success; however, intravenous administration of prostaglandin E_1 is the more reliable treatment. Long-term side effects include periosteal thickening,[75] which can cause painful swelling of the hands and feet and can be seen in the ribs on chest radiographs. There are also reports of a higher prevalence of pyloric stenosis in babies who have received long-term treatment with prostaglandin E_1.[55]

Heart Rate

The importance of heart rate and rhythm as a determinant of myocardial performance must be decided clinically. The neonate with congenital complete atrioventricular (AV) block might be well, and the postoperative neonate with a comparable rate and rhythm might need pacing. Similarly, supraventricular tachycardia that is tolerated by the normal neonate for at least 24 hours causes low output and low blood pressure in a postoperative baby. Details of the evaluation and treatment of arrhythmias, including those seen after cardiac surgery, are discussed in Part 9.

Preload

The clinical assessment of preload is indirect and includes serial measurement of body weight, liver size, and tissue fluid. Unfortunately, these parameters might not reflect the quantity of intravascular fluid. Atrial and ventricular end-diastolic pressures are more quantitative but are also affected by ventricular diastolic function and AV and semilunar valve function. Because the goal is to produce an adequate cardiac output and blood pressure, the preload that is needed is also determined by ventricular contractility and afterload. In clinical practice, if the baby is well perfused and has good blood pressure and urine output, preload is adequate. If the lungs are clear and there is no evidence of pleural fluid or ascites, fluid overload is not present.

Several specific fluid issues apply to the postoperative neonate. After cardiopulmonary bypass, even with the current techniques of ultrafiltration when bypass is being terminated, total body fluid is increased. Routine daily fluid administration should be less than calculated maintenance. This could require concentration of medications or hyperalimentation or, in the days after surgery, enteral feedings. Blood losses should be replaced to maintain the hematocrit, and coagulopathies should be corrected with fresh frozen plasma or platelets as indicated. If perfusion, blood pressure, or urine output is reduced, the role of hypovolemia should be assessed by analysis of fluid balance and atrial pressures. Low atrial pressures or atrial pressures that have been falling are the best sign that intravascular volume is depleted. Fluid administration helps improve the cardiac output in a baby with impaired contractility; however, it usually is at the cost of increased body fluid and does not address the fundamental physiologic problem.

Diuretics are commonly used to improve fluid balance in the preoperative and postoperative neonate. Tachypnea, hepatomegaly, inappropriate weight gain, or pulmonary edema on a chest radiograph are typical signs of fluid overload requiring treatment with oral or intravenous diuretics. Depending on the degree of physiologic impairment, furosemide and bumetanide, each used alone or in combination with chlorothiazide, are the most commonly used diuretics. Oral metolazone has been used to manage chronic fluid retention. The addition of spironolactone, a potassium-sparing diuretic, or potassium chloride supplements is important in treating the inevitable hypokalemic, hypochloremic alkalosis that results from long-term diuretic therapy.

Afterload

Systemic arterial afterload reduction has become an important short- and long-term treatment for ventricular dysfunction or AV valve regurgitation.[3,27] The clearest indication for afterload reduction is the combination of normal blood pressure, normal filling pressures, and poor peripheral perfusion in the postoperative baby. Selective intravenously administered vasodilators, such as nitroprusside, have the advantage of very short duration of action and dosing titrated to effect. Dobutamine has both short-acting inotropic and vasodilator properties. Amrinone and milrinone have excellent and longer-acting inotropic and vasodilator effects. Of all the orally administered agents, captopril is still the most commonly used in neonates. Renal function and potassium levels must be monitored, especially in babies with poor renal perfusion. Pulmonary vasodilators are discussed in Part 8 under "Persistent Pulmonary Hypertension (Persistent Fetal Circulation)." In the postoperative baby, recognition and management of pulmonary hypertension is often facilitated by pulmonary artery monitoring lines, which permit assessment of the response to therapy.

Systemic afterload augmentation is rarely needed in the neonate. Treatment of cyanotic spells before surgery or decreased arterial saturation after a systemic-to-pulmonary shunt can include increasing the systemic vascular resistance with phenylephrine. By changing the relative systemic and pulmonary resistance, more flow is directed through the shunt or pulmonary valve. Similarly, increasing the pulmonary vascular resistance by decreasing the inspired oxygen, while avoiding hyperventilation or bleeding carbon dioxide into the ventilator circuit, might be needed for the baby with excessive pulmonary blood flow. This is most important in babies with single-ventricle physiology who have limited ventricular functional reserve.

Contractility

Orally administered digoxin has been used for decades to treat congestive heart failure. Its safety in older children is well established, and with dose modifications, it may be used in the neonate.[28] Toxic effects are rare but can be treated with digoxin-specific Fab fragments.[76] There remains considerable skepticism about the efficacy of digoxin in babies with left ventricular volume overloading, and in some centers, digoxin is reserved for treating arrhythmias and overt ventricular dysfunction. When other oral inotropic agents are unavailable, and with appropriate care in dosing, digoxin can have a role in the treatment of these and other babies with congestive heart failure.

There is also considerable experience with intravenous administration of β-adrenergic blocking agents in preoperative and postoperative management of ventricular dysfunction with low cardiac output or low blood pressure. Contractility is the physiologic problem when there is low cardiac output and adequate atrial pressures for the clinical situation. Decreased wall motion, as shown by postoperative echocardiography, especially if systemic vascular resistance and blood pressure are not high, also suggests impaired contractility.

Dopamine and dobutamine[8] have a similar inotropic effect.[10] Dobutamine causes somewhat more tachycardia and can be associated with hypotension as a result of systemic vasodilation. Premature babies usually have a greater blood pressure response to dopamine.[26,35] Epinephrine in low doses is a potent inotrope with acceptable chronotropic and peripheral vasoconstriction, which can be a problem at high doses. Isoproterenol has inotropic, chronotropic, and some systemic and pulmonary vasodilatory effects. Tachycardia often limits its usefulness. Amrinone is a longer-acting intravenously administered inotrope that acts by increasing cyclic adenosine monophosphate by inhibiting phosphodiesterase. It has excellent inotropic and peripheral vasodilator effects.[40] Its principal side effect is thrombocytopenia. Milrinone improves cardiac index and lowers systemic resistance after cardiac surgery in neonates.[31] Milrinone should be used with caution in neonates with renal failure.

Long-term intravenous administration of inotropes increases the risk for development of diastolic dysfunction and receptor downregulation. Every effort should be made to wean the baby from these medications on the basis of clinical and invasive monitoring.

Treatment of Cyanotic Spells

Although cyanotic spells are most common at several months of age, they can occur in the first month of life. If the initial spell is atypical and is not preceded by crying or occurs without the hyperpnea, the possibility must be considered that a previously unrecognized patent ductus arteriosus has closed. Prompt recognition and treatment of spells can prevent the neurologic and metabolic sequelae of severe, prolonged hypoxia (Box 45-16). Some of the therapy is based on clinical observations dating back to the early experience with the Blalock-Taussig operation; newer therapies have been based on further thoughts about the pathophysiology of spells.

Supplemental oxygen, in theory, should not have much effect in babies with markedly diminished pulmonary blood flow, but it continues to be used. Morphine, and more recently fentanyl, might work by decreasing endogenous catecholamines and reducing dynamic subpulmonary obstruction. Similarly, propranolol blocks the effect of endogenous catecholamines. This cannot be the only effect because these drugs appear also to help babies with pulmonary atresia and spells who cannot have increased dynamic infundibular obstruction. Increasing systemic resistance with phenylephrine drives more blood into the lungs if there is no change in pulmonary vascular resistance.

Fluid administration probably helps either by increasing end-systolic volume and reducing dynamic infundibular obstruction or by increasing arterial blood pressure. The prolonged hypoxia causes metabolic acidosis, which should be treated with sodium bicarbonate.

Some babies with refractory spells respond to intubation and hyperventilation, which suggests that there is a component of pulmonary vascular reactivity. Anesthetic doses of fentanyl can be added once the airway and ventilation are secure. Finally, urgent repair or a shunt might be considered on the basis of the underlying anatomy.

Prevention of Bacterial Endocarditis

Bacterial endocarditis is an exceedingly rare and isolated problem in early infancy. Occasional babies have endocarditis or endovascular infections after cardiac surgery or as a complication of prolonged vascular access.[51] The once well-established recommendations for antibiotic prophylaxis were dramatically modified in 2007 and are now limited to individuals with unrepaired cyanotic heart defects, prosthetic valves, and heart transplantation or who have had prosthetic material placed within the last 6 months either by surgery or cardiac catheterization.[74]

BOX 45–16 Treatment of Cyanotic Spells

Oxygen
Intubation and hyperventilation
Morphine, 0.1-0.2 mg/kg IV or SC
Fentanyl, 1-4 μg/kg
Ketamine, 1 mg/kg IV
Fluid (5% albumin, blood if anemic), 5-20 mL/kg
Sodium bicarbonate, 1 mEq/kg IV
Propranolol, 0.05-0.15 mg/kg slow IV
Phenylephrine, 0.01 mg/kg IV, 0.1 mg/kg SC or IM;
  1-20 μg/kg/min IV

IM, intramuscularly; IV, intravenously; SC, subcutaneously.

Although many neonates will fit into these categories, the procedures which result in bacteremia are either uncommon or not performed in neonates, and thus prophylactic antibiotics are often used empirically rather than based on evidence of need or efficacy. Furthermore, many babies who have gastrointestinal, genitourinary, or tracheal surgery are often receiving antibiotics for other reasons.

Two situations arise that might not warrant prophylactic antibiotics. Transesophageal echocardiography has a low incidence of bacteremia and no documented relationship to endocarditis in adults. Circumcision has been performed for centuries on babies with congenital heart disease, without endocarditis as a known complication. There are no recommendations from the American Heart Association or the American Dental Association, and local or individual preference dictates whether to administer one dose of amoxicillin orally before and one after neonatal circumcision to babies with heart defects.

Surgery

The ingenuity of neonatal cardiovascular surgery has dramatically improved the prognosis for babies with heart disease. Many surgical procedures have been named after the innovative surgeon who first reported the advance (Table 45-12). Specific surgical management is discussed under the individual lesions. The general principles of surgery—accurate preoperative diagnosis and careful correction of defects with preservation of myocardial and, when possible, valvular function—pertain to all surgeries. Residual defects, obstruction, and valve incompetence are less likely to be tolerated in the neonate. Moderate hypoxia is usually preferable to excessive volume loading for large systemic-to-pulmonary shunts in babies with pulmonary atresia (including hypoplastic left heart syndrome) after neonatal palliation. The mortality rate for neonatal heart surgery for many defects is low, and attention has been focused on strategies to reduce morbidity. The deleterious effects of circulatory

TABLE 45–12 Named Operations

Procedure	Operation
Systemic-to-Pulmonary Shunts	
Blalock-Taussig	Anastomosis of subclavian artery to pulmonary artery
Waterston	Anastomosis of ascending aorta to right pulmonary artery
Potts	Anastomosis of descending aorta to left pulmonary artery
Gore-Tex*	Vascular graft of expanded polytetrafluoroethylene
Closed Heart Procedures	
Brock	Closed pulmonary valvotomy
Blalock-Hanlon	Closed surgical atrial septectomy
Waldhausen	Subclavian flap angioplasty for coarctation of the aorta
Glenn	End-to-end anastomosis of SVC to RPA
Open Heart Procedures	
Jatene	Arterial switch for D-transposition of the great arteries
Mustard	Intra-atrial pericardial baffle for D-transposition of the great arteries
Senning	Intra-atrial baffle using mostly the atrial septum and walls for D-transposition of the great arteries
Rastelli	Extracardiac conduit for treatment of pulmonary atresia
Bidirectional Glenn	End-to-side anastomosis of SVC to RPA; often done as a “hemi-Fontan” procedure with anastomosis of proximal SVC to underside of RPA, but patching over of this opening until completion of modified Fontan
Modified Fontan	Anastomosis of right atrium (proximal SVC) to pulmonary artery, with intra-atrial baffling of IVC to proximal SVC; done at same time as or after bidirectional Glenn
Damus-Kaye-Stansel	Anastomosis of main pulmonary artery to ascending aorta, to bypass subaortic obstruction in single ventricle
Norwood	First stage: anastomosis of proximal pulmonary artery to hypoplastic ascending aorta, systemic-to-pulmonary shunt, atrial septectomy Second stage: bidirectional Glenn Third stage: modified Fontan
Sano	Right ventricle to pulmonary artery conduit as part of Norwood palliation.

*Named after the founders of the company that developed the polytetrafluoroethylene (Gore-Tex) graft.

IVC, inferior vena cava; RPA, right pulmonary artery; SVC, superior vena cava.

arrest have been carefully documented in babies with transposition of the great arteries, which favors, when possible, low-flow cardiopulmonary bypass over circulatory arrest for neonates.[7]

Neonatal Heart Transplantation

Neonatal heart transplantation initially focused on the baby with hypoplastic left heart syndrome and was driven by the disappointing early results with the Norwood operation and by the improved survival rate after adult cardiac transplantation with the introduction of cyclosporine as an immunosuppressive agent. Bailey,[4] at Loma Linda University, performed a xenotropic heart transplantation (on Baby Faye) in 1983, and this was followed by the first orthotropic heart transplantation for hypoplastic left heart syndrome in 1985. Although the results with surgical palliation of hypoplastic left heart syndrome have improved, there remains an interest in and an acceptance of transplantation for hypoplastic left heart syndrome and severe neonatal myopathies.

Clinical experience and experimental studies suggest that the newborn period might be a particularly favorable time for transplantation because of the immaturity of the immune system and low levels of antibody. This tolerance is further demonstrated by the transplantation of ABO-incompatible hearts in infants.[73]

Preoperative assessment and careful hemodynamic management are important because limited donor availability dictates careful recipient selection and waiting times of up to several months. Anatomic variants of hypoplastic left heart are not impediments to transplantation, although precise definition of pulmonary venous drainage is important. Pretransplantation evaluation by the transplant team maximizes the family's understanding of the long-term commitment needed for transplantation.

In view of the high incidence of genetic and neurologic malformations, screening studies including chromosome analysis and cranial and renal ultrasonography are performed on all babies. During the waiting period, medical management based on an understanding of single-ventricle physiology can minimize pulmonary blood flow and favor systemic blood flow. Pulmonary venous hypertension caused by a restrictive atrial septal defect and poor ventricular function are major limitations to successful medical management. Careful monitoring for infection, strict adherence to central venous line technique, and early nutrition are as important as therapy with prostaglandin E_1 to the survival of infants awaiting a transplant. Blood transfusion, when necessary, is with irradiated, cytomegalovirus-negative, leukocyte-filtered blood. There has been interest in the successful use of erythropoietin to minimize blood transfusions in neonates awaiting transplant surgery.[62]

The surgical technique for neonatal heart transplantation for hypoplastic left heart syndrome is now well developed.[58] Particular attention to the distal aortic anastomosis and wide excision of the ductus arteriosus minimize the subsequent development of coarctation of the aorta. Impaired ventricular function in the immediate postoperative period is managed with conventional inotropic drugs or with extracorporeal membrane oxygenation if profound dysfunction threatens survival. Postoperative pulmonary hypertension can occur, particularly in neonates who have had highly restrictive atrial septal defects and pulmonary venous hypertension. Death before transplantation and prolonged average waiting times remains a challenge.[17] ABO-incompatible donors[72] and transplantation after donor cardiocirculatory death[14] have been used in newborns to help overcome this problem.

Prevention, assessment, and treatment of rejection are a significant long-term challenge. Immunosuppression protocols generally start with tacrolimus, prednisone, and mycophenolate mofetil.[2] Most neonates can be successfully weaned from steroids during the first few months after transplantation.[16] Rejection surveillance is by clinical, electrocardiographic, echocardiographic, and myocardial biopsy criteria.[41] Clinical criteria for rejection include fever and irritability. Unfortunately, these symptoms are common in young infants and can be nonspecific. Close follow-up is essential in identifying subtle signs that can suggest rejection rather than intercurrent illness. Electrocardiographic and echocardiographic changes, including voltage, wall thickness, and systolic and diastolic ventricular function, can supplement the clinical assessment; however, they are not generally reliable.[49] Dobutamine stress testing has been used to identify transplant patients at risk for cardiac events.[20]

Mild rejection can cause a decreased rate of posterior wall thinning. Increased left ventricular mass, especially if associated with changing systolic function, suggests severe rejection. Myocardial biopsy is possible but technically more challenging in neonates.[77] In neonates, biopsies rarely identify rejection when it is not suspected clinically, and biopsy specimens show negative results about 50% of the time when rejection is clinically evident. In the Loma Linda neonatal experience, the median number of rejection episodes is one, which usually occurs in the first 3 months.

Side effects of immunosuppression have improved with newer protocols. Growth and bone strength are rarely a problem in neonates rapidly weaned from steroids. Cyclosporine-associated renal dysfunction and hypertension occur in more than half of the babies. These side effects are dose related, and lower doses after the first year are stabilized or improve the effect. Both problems are much less prevalent with the use of tacrolimus. Hirsutism and gingival hyperplasia, although not medically harmful, are of cosmetic concern for the children and their families. Lymphoproliferative diseases have been reported with older children and adults and can be anticipated with infants after transplantation.

Opportunistic infections remain a constant threat to immunocompromised patients, and prophylactic antibiotic and antiviral agents are occasionally used, especially in the immediate post-transplantation period.[13] Cytomegalovirus-related pneumonia and gastrointestinal and blood infections are the most common. In children, they usually are caused by preexisting infection or the use of infected donors. Routine blood cell counts and electrolyte measurements are essential in following up the impact of the immunosuppressive agents on bone marrow and renal function. Immunization with killed vaccines is appropriate.

The 5-year survival rate is 72%; however, most deaths occur within the first month.[17] For babies with hypoplastic left heart syndrome, survival rate at 5 years must also include the proportion of babies who die awaiting transplantation. When this pretransplantation mortality rate is considered, the 5-year survival rate falls to 54%.[17]

Graft survival is not ensured, and dramatically premature atherosclerosis could require retransplantation or lead to sudden death. Graft atherosclerosis occurs in about 7% of children an average of 2 years after transplantation.[52] It does appear to be more prevalent in children with multiple episodes of rejection. The only effective treatment in young children at present is retransplantation, although newer immunosuppressive drugs, including rapamycin, hold promise to both prevent and treat graft vasculopathy.[45] Cholesterol-lowering drugs appear to reduce the risk for graft vascular disease.[71]

Pediatric follow-up data from the 2008 report of the Registry for International Society for Heart Transplantation indicate that for babies undergoing transplantation in the first year of life, the survival over the next 4 years is 88% for those who survive the first year after the transplantation.[34] Hypertension, renal dysfunction, hyperlipidemia, graft atherosclerosis, and malignancies remain important long-term issues.[17,34,69] Neurodevelopmental follow-up of infant heart transplant recipients demonstrates low-normal functional status.[6]

NEONATAL INTERVENTIONAL CATHETERIZATION

Catheter-directed therapies for congenital and acquired heart disease were described more than 40 years ago. However, balloon atrial septostomy, which was introduced in 1966, was the first to be widely and successfully used in pediatrics.[57] Since the mid-1980s, the variety of interventions has increased dramatically and now includes blade septostomy; balloon septal angioplasty; balloon dilation of stenotic valves, arteries, and veins including native or postoperative coarctation of the aorta and stenotic central or branch pulmonary arteries; occlusion of various types of congenital and acquired vascular lesions; cutting balloon dilations for resistant lesions; radiofrequency wire perforation of atretic valves or imperforate atrial septum; and endovascular stent implantation including for neonatal indications. Many procedures, such as balloon dilation of valvular pulmonary stenosis, are now considered first-line therapy, and with increased clinical experience and the evolution of less traumatic and smaller catheter and delivery systems, most of these procedures are now successfully and safely performed in the newborn infant.

Creation of Atrial Septal Defects

INDICATIONS

The initial therapy for transposition of the great arteries in neonates is balloon atrial septostomy, even when primary repair is to be performed in the newborn period. In addition, septostomy is indicated when an unrestrictive atrial shunt is mandatory, as in absent right or left AV connection or valve atresias, pulmonary atresia with intact ventricular septum, or total anomalous pulmonary venous connection balloon. Despite surgical advancements facilitating early surgical repair for many complex lesions, balloon septostomy remains a vital treatment modality in infants with lesions including absent AV connection, in whom primary repair is not feasible in the neonatal period.

TECHNIQUES

Balloon Atrial Septostomy

The basic technique for balloon atrial septostomy has remained essentially unaltered since originally described by Rashkind and Miller in 1966.[57] Modifications in catheters have made the procedure simpler and more effective. Percutaneous femoral or umbilical access has essentially eliminated the need for venous cutdown, and the use of a larger balloon that accommodates 4 mL of fluid has resulted in a larger effective dilating diameter (Fig. 45-27). The procedure traditionally has been performed in the cardiac catheterization laboratory; however, it has been increasingly performed at the bedside under ultrasound guidance, which can expedite correction of hypoxia in the very fragile infant.

The tear occurs in the valve of the foramen ovale. Success can be assessed by an increase in arterial oxygen saturation, by equalization of atrial pressures, and by two-dimensional echocardiographic imaging and Doppler flow studies across the defect created.

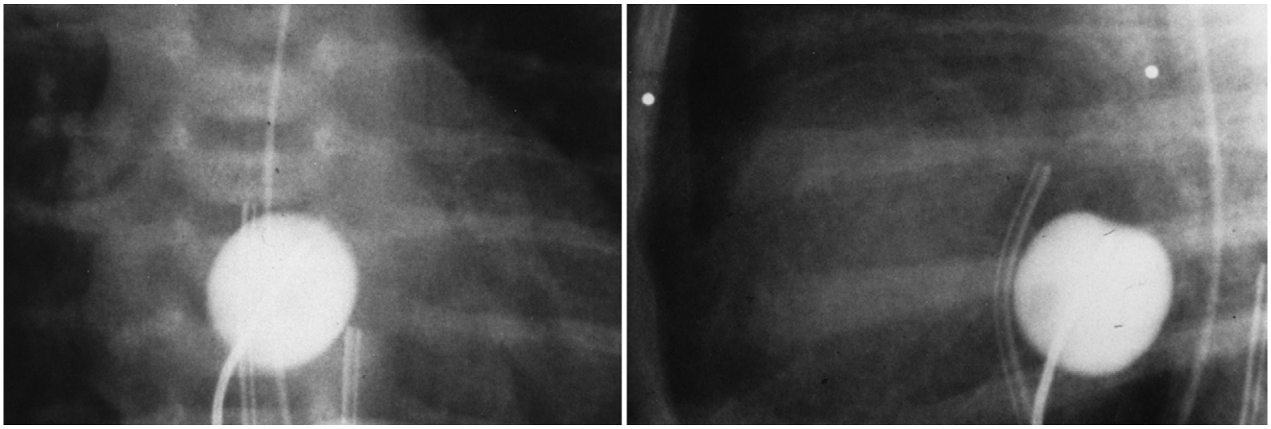

Figure 45–27. Anterior (*left*) and lateral (*right*) projections of inflated 4-mL septostomy balloon in the left atrium of a neonate with transposition of the great arteries before withdrawal into the right atrium across the atrial septum.

There are no absolute contraindications to balloon septostomy; however, the procedure cannot be performed in the absence of the hepatic portion of the inferior vena cava (azygos continuation) and is difficult when the left atrium is hypoplastic (i.e., hypoplastic left heart syndrome) or there is left juxtaposition of the right atrial appendage. In the latter two conditions, fluoroscopic guidance may be useful in addition to echocardiographic imaging in facilitating proper catheter position.

Serious complications are rare but can include perforation and tearing of the atrial wall or pulmonary veins or rupture of the tricuspid valve. Such complications require prompt recognition but may not be fatal. Atrial dysrhythmias are usually transient. Cerebral complications caused by an embolus or subarachnoid hemorrhage and pneumopericardium have also been reported but are similarly rare and can be virtually eliminated by careful catheterization and imaging techniques.

Blade Atrial Septostomy

Beyond the first weeks of life, balloon atrial septostomy is rarely successful because of thickening of the atrial septum. Through experimental studies, a blade atrial septostomy catheter was developed for such clinical situations, and its feasibility, efficacy, and safety were established.[53] This technique was previously employed primarily in patients with transposition of the great arteries and poor atrial mixing; however, with implementation of primary atrial or arterial repairs in the newborn period, this population no longer exists. In neonates, other techniques have supplanted its usefulness in addressing problematic atrial septal restriction.

The main indication remains in older infants and children with an absent left or right AV connection, who require an unrestrictive atrial communication and in whom the atrial defect has become progressively smaller with age. It has also been used in children receiving extracorporeal membrane oxygenation for acute myocarditis to decompress the left atrium, although atrial septal angioplasty with or without stent placement is becoming a more accepted approach to this problem.[61]

Balloon Septal Angioplasty and Stent Placement

Some infants who require an atrial septal defect to relieve left atrial hypertension have an extremely small left atrium, either because of associated left heart hypoplasia or because of leftward deviation of the attachments of the septum primum. The atrial septum in these infants is usually thick but also might be intact with decompression of the pulmonary veins through other routes. In these infants, the risk for atrial laceration with either balloon or blade septostomy is high, and adequate palliation might be technically impossible with either technique. In this circumstance, the successful creation of an adequate atrial septal defect has been achieved by performing atrial septal puncture, followed by balloon dilation, with or without stent placement. The creation of multiple holes in the atrial septum might be required. This procedure is particularly useful in the patient with hypoplastic left heart syndrome and a severely restrictive atrial septal defect, before either first-stage surgical palliation or cardiac transplantation. Radiofrequency perforation wires currently play an important role in facilitating transeptal puncture in the setting of an imperforate or thick atrial septum, and are technically better suited to neonatal interventions than traditional transseptal needles (Brockenbrough needles).

Valvuloplasty

PULMONARY VALVE STENOSIS

Extensive experience in children and adults has convincingly demonstrated that percutaneous balloon dilation of the pulmonary valve can effectively reduce the transvalvular gradient to a degree equivalent to that of a surgical valvotomy, thus avoiding the need for open heart surgery.[33] The cyanotic newborn infant with critical pulmonary stenosis and an intact ventricular septum requires emergent treatment. Surgical valvotomy with or without a pulmonary-to-systemic shunt had been the traditional approach. With experience in percutaneous balloon valvotomy in the older child, the technique was successfully adapted to the neonate.

Pulmonary valve dilation in the neonate with critical pulmonary stenosis is a technically somewhat more challenging procedure than in older children; the most difficult aspect is crossing the pinpoint orifice of the pulmonary valve (Fig. 45-28). Gradient relief, however, is reported to be comparable to that achieved by balloon dilation in older children and by surgery in neonates.

The immediate postprocedure gradient might not accurately reflect relief of obstruction in infants who have a patent ductus arteriosus; however, subsequent noninvasive imaging usually confirms adequate and often persistent relief of obstruction. Less ideal candidates for the procedure might have associated right ventricular or tricuspid valve hypoplasia or a poorly expanded subpulmonary infundibulum. Although complications (annular or venous tears, cardiac perforation) in neonates

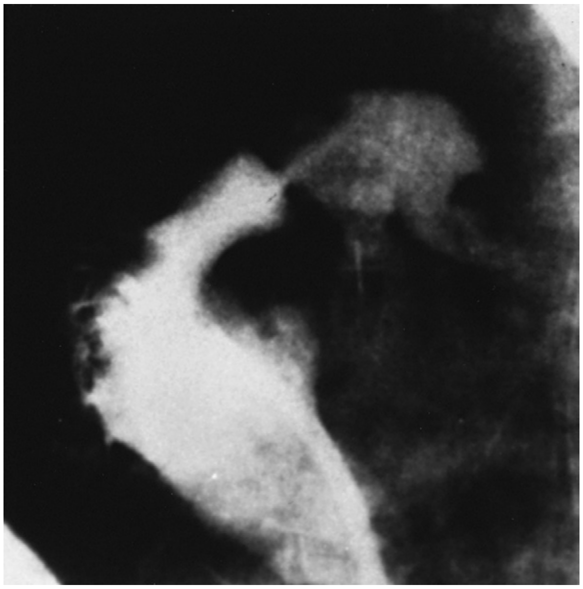

Figure 45–28. Lateral projection of right ventriculogram of a neonate with critical pulmonary stenosis. Note pinpoint central jet with poor filling of main pulmonary artery.

had been reported at significantly higher rates than in older children, with contemporary equipment and approaches, the incidence of serious complications is certain to be much lower.[15] Even infants with complete membranous atresia of the pulmonary valve can be effectively decompressed by wire-guided perforation of the valve followed by balloon dilation.[70]

BALLOON DILATION OF THE PULMONARY VALVE IN COMPLEX CONGENITAL HEART DISEASE

Balloon dilation of a stenotic pulmonary valve in cyanotic heart defects, including single ventricle with pulmonary stenosis and tetralogy of Fallot, can eliminate the immediate need for a systemic-to-pulmonary shunt, which has risks that include pulmonary artery distortion. The balance between the severity of the obstruction at the valvular level and severity at the subvalvular level reflects the success of the procedure.

Despite a number of reports,[30,47] its role remained controversial. Sreeram and coworkers[65] reported 82 successful procedures in patients with tetralogy of Fallot, with arterial oxygen saturation increasing from an average of 74% to 90.5%. Of 67 patients, 11 required an aortopulmonary shunt within 1 month of dilation. Serious complications occurred in 4 patients and included transient pulmonary edema (1 patient), sepsis (1 patient), and cardiac tamponade requiring emergency surgical repair (2 patients). More encouraging results were demonstrated recently after right ventricular outflow tract stent placement in symptomatic infants with tetralogy of Fallot. In these 9 patients, median arterial saturation increased from 73% to 94%, with most infants going on to complete repair at a later age. In these patients, the pulmonary valve and annulus were thought to be inadequate to avoid ultimate transannular patching, and this strategy was employed to allow definitive, complete repair to take place at a more favorable age and size.[21]

PULMONARY VALVE ATRESIA

The traditional surgical approach to pulmonary valve atresia in neonates consists of creating a systemic-to-pulmonary artery shunt, together with an open pulmonary valvotomy or right ventricular outflow patch at the same or a later procedure. Currently, percutaneous transcatheter techniques can help avoid neonatal surgery. Typically, this involves perforation of the atretic valve with radiofrequency wires, followed by balloon dilation.

The long-term efficacy of these techniques is encouraging, with results comparable to surgery in selected patients.[1] Moreover, infants with a problematic degree of right-to-left atrial shunting due to associated tricuspid and right ventricular hypoplasia, stenting of the ductus arteriosus can be performed concomitantly to augment pulmonary blood flow in lieu of a surgical aortopulmonary shunt, allowing time for beneficial right heart remodeling and growth. Use of this strategy in appropriate patients can allow for establishing biventricular circulation, without surgery, in most patients.[46]

AORTIC VALVE STENOSIS

Balloon dilation of congenital aortic valve stenosis in children was initially reported by Lababidi in 1983.[39] Application of this technique to neonates with critical aortic stenosis followed shortly thereafter. As in the case of pulmonic stenosis, the technical considerations and risks of the procedure differ for neonates from those for infants and children. Balloon dilation remains an important treatment for neonates with critical aortic stenosis. The mortality rate among neonates with this lesion was initially high, whether treated surgically or by interventional catheterization. The neonatal mortality rate for critical aortic stenosis was 18% versus 0.5% in children beyond the neonatal period, with serious morbidity in 36% of neonates versus 0.2% of children in the older group.[59] Careful selection of patients and improved techniques have resulted in good results even in ductal-dependent neonates with aortic stenosis.[22]

For neonates judged to have favorable anatomy for balloon valvuloplasty, the valve is often approached retrograde through the femoral or umbilical arteries, although the valve can also be successfully crossed antegrade from the left ventricle after the crossing the atrial septum. Alternatively, accessing the right carotid artery through a surgical cutdown provides a technically straightforward approach to the valve and appears to be well tolerated.[12]

Given the disorganized nature of the valve and its eccentric opening, crossing the valve with a guide wire can, at times, be difficult. Inadvertent wire perforation of the valve leaflet and subsequent dilation, or avulsion of the leaflet from the aortic ring, has been described and can result in severe aortic regurgitation. Although there has been a dramatic reduction in catheter and sheath size, femoral artery trauma or thrombosis can still occur in neonates but often favorably responds to medical therapy with heparin or thrombolytics, or both.

MITRAL VALVE STENOSIS

Percutaneous balloon dilation of rheumatic mitral stenosis was first described in 1984 and in children the following year; application of the technique to congenital mitral stenosis was reported in 1986. In patients with congenital mitral stenosis, results are variable. Among nine patients reported by Moore and associates,[48] seven had a significant immediate increase in valve area and decrease in mean gradient, although two of those had evidence of restenosis within 2 months of the procedure. Experience with neonates is extremely limited.

Angioplasty

NATIVE COARCTATION OF THE AORTA

Coarctation of the aorta traditionally has been treated by surgery. Although a variety of surgical techniques have been employed, there has been a low mortality rate, especially in those infants without additional congenital heart defects and managed with preoperative prostaglandin E_1 to maintain peripheral perfusion. However, the recurrence rates range between 10% and 30%, which has prompted alternative strategies for management. Balloon angioplasty of recurrent aortic coarctation in a critically ill infant was first reported by Singer and colleagues[64] in 1982. Experimental work in excised segments of human coarctation and in animal models demonstrated that successful balloon dilation required relatively high pressures and was associated with tears of the intima and media; the adventitia remained intact.[43] This finding generated concern about late aneurysm formation and has led to considerable controversy over the issue of whether native coarctation of the aorta should undergo angioplasty. Aneurysm formation has been reported in a small number of children, although long-term follow-up, of large numbers of patients, is incomplete.

Successful gradient relief has been reported, although primarily it has been accomplished in the older infant and child. Experience suggests that in the newborn period, however, gradient relief can be transient and obstruction recurs, requiring further intervention.[54,56] As in any arterial intervention in the neonate, femoral arterial complications are more frequent. To prevent these complications, successful coarctation angioplasty can be performed from the venous anterograde approach. The current role of angioplasty in native coarctation, in most centers, is as a selective palliative technique that allows for hemodynamic and clinical stabilization in neonates deemed high-risk surgical candidates.

RECURRENT COARCTATION OF THE AORTA

Surgery for recurrent coarctation is not uniformly successful and can be technically difficult because of surgical scarring. Balloon angioplasty for recurrent coarctation has been very effective in this setting.[29] The type of initial repair does not appear to influence the outcome of balloon angioplasty. Angioplasty typically is not performed until 6 to 8 weeks after the initial operation in order to prevent inadvertent rupture of the suture line. Under these circumstances, the surgical scar, which is the major component of the recurrent obstruction, limits the extent of the tear. As in any arterial intervention, femoral artery complications are a possible complication. The incidence of late aneurysm formation is unknown. The procedure has become the initial management approach in this patient group. Coarctation restenosis has been recognized as a common complication of the first stage of the Norwood procedure and appears to respond to balloon dilation.[67]

PERIPHERAL PULMONARY ARTERY STENOSIS

Pulmonary artery stenosis beyond the hilum and diffuse hypoplasia of the pulmonary arteries are difficult or impossible to treat surgically. Rehabilitation of branch pulmonary artery stenosis by balloon dilation and endovascular stents has been useful in infants and children with challenging pulmonary artery anatomy.[39,78] When the outcome after surgical repair of associated lesions is heavily dependent on correction of peripheral pulmonary artery stenoses, as in some children with tetralogy of Fallot and in those with single ventricle physiology who will eventually undergo a Fontan repair, it seems advantageous to be able to assess and palliate important pulmonary stenoses preoperatively. Early balloon dilation of branch pulmonary artery stenoses can afford maximal growth potential coincident with somatic growth. The use of endovascular stents in infants currently is limited by the largest stent diameter that can be reached through sequential dilations with somatic growth. Although many stents can be delivered even in the neonatal setting, they might not suffice from the standpoint of ultimate adult vessel diameter and require surgical revision or removal. Ongoing research is focusing on the development of stents that are either biodegradable or can be disarticulated in situ by balloon dilation, thus freeing the vessel to be further dilated if needed. Cutting balloons, angioplasty balloons with an array of longitudinal microtomes, have provided a useful tool in addressing severe peripheral arterial stenoses, especially in the setting of genetic arteriopathies, such as seen in Williams syndrome.[9] Their use in neonates, however, is limited.

PULMONARY VEIN STENOSIS

The results of surgical treatment of pulmonary vein stenosis are poor, and even when improvement occurs, early recurrence is common. Early reports of balloon angioplasty, as well as of the use of balloon-expandable endovascular stents, have indicated that, like surgery, dilation is short lived, and recurrent obstruction dominates the clinical picture.[50]

DILATION OF SURGICALLY CREATED SHUNT BETWEEN THE SYSTEMIC ARTERIAL AND THE PULMONARY ARTERIAL CIRCULATION

Neonates requiring a shunt between the systemic arterial and the pulmonary arterial circulations might have progressive cyanosis postoperatively because of kinking or stenosis at the shunt site. On the basis of limited early experience, it appears that this type of narrowing can be amenable to balloon dilation or, more reliably, stent placement using low-profile coronary or other premounted stents. Obviously, if profound cyanosis is present, emergent surgical shunt revision is warranted.

Stents to Maintain Patency of the Ductus Arteriosus

In infants who have ductus-dependent heart defects, long-term prostaglandin E_1 infusion has multiple side effects. Several investigators have attempted to maintain ductal patency through stent implantation, which could replace surgical creation of a shunt from the systemic to the pulmonary circulation.[18] Previous experience focused on infants who had hypoplastic left heart syndrome and were awaiting heart transplantation. Recently, however, the evolution of a “hybrid approach” to the treatment of these patients has made stent placement in the ductus arteriosus commonplace at centers that have adopted this approach. Typically, this is done by a sternotomy through a small pursestring incision in the main pulmonary artery under fluoroscopic guidance and using both surgical and medical expertise.[24] Neonates with ductal dependent pulmonary blood flow, similarly, can be candidates for maintaining ductal patency through endovascular stenting in lieu of a surgical aortopulmonary shunt.[25] These infants typically undergo placement of premounted coronary stents to achieve an appropriate ductal diameter.

Vessel Occlusion

Embolization or occlusion of abnormal vascular communications is possible with a variety of materials, including coils, tissue adhesives, detachable balloons, foam, and umbrella devices. Vessels and defects successfully treated by transcatheter therapy include aortopulmonary collateral vessels; systemic circulation pulmonary artery shunts; patent ductus arteriosus; atrial and ventricular septal defects; and a variety of arteriovenous malformations involving the hepatic, pulmonary, coronary, or cerebral circulations. The effectiveness of occluding aortopulmonary collateral vessels, which develop in infants with bronchopulmonary dysplasia, has not been established; the emergence of a new collateral supply is likely.

The usefulness of these techniques in the treatment of neonates is determined by the size of the device or delivery systems. Coils that can be delivered through 4-Fr systems are most applicable to the neonate. Coil occlusion of patent ductus arteriosus has become the treatment of choice for infants and children with persistent ductal patency.[32] Neonates in this group, most of whom are infants with low birthweight, largely remain treated by surgery because of the technical limitations of interventional procedures. Newer generation, nitinol-based occluders are available for atrial septal defects and patent ductus arteriosus, and, although the indications in neonates are uncommon, these occluders could be delivered through a percutaneous approach in certain situations. A range of devices for ventricular septal defects are available but would probably have limited utility in the neonatal population, unless delivered by periventricular approach in the operating room.

Line Placements: Transhepatic Catheterization

In some children with congenital heart disease, as well as in chronically ill neonates, conventional venous access (femoral, subclavian, or internal jugular veins) might become unavailable. The technique of percutaneous transhepatic venous access for cardiac catheterization or with subsequent Broviac insertion for long-term administration of parenteral nutrition or antibiotics has been used and in short-term follow-up provides an effective and safe alternative in children.[63] As more experience with the technique evolves, this could prove to be a preferred route for percutaneous venous access in certain children.

Endomyocardial Biopsy

Endomyocardial biopsy has proved to be a safe and effective means of diagnosing a wide variety of myocardial diseases in the older child and adult. Although the indications are rare (myocarditis, cardiomyopathies, after neonatal heart transplantation, metabolic disease), it can be safely performed in neonates and infants. No significant complications have been reported, although using a soft size 3-Fr bioptome, often with echocardiographic and fluoroscopic guidance, is recommended to minimize the risk for cardiac perforation.

Catheter Retrieval of Foreign Bodies

The first catheter retrieval of a foreign body from a child's heart was reported by Rashkind and Miller in 1966.[57] An international review of experience with this procedure reported 90% success with no complications in 180 retrievals.[11] Embolization of sheared catheter fragments or lost guide wires is a ubiquitous (albeit preventable) event. Even in very small infants, such fragments can be safely retrieved from the heart or vasculature percutaneously with the use of a snare, forceps, or basket.

Procedural Complications

Complications during interventional studies are more common in the neonate because of hemodynamic and biochemical instability. As with diagnostic procedures, diligent patient monitoring is performed, with particular attention paid to the neonate's vital signs, blood volume, hemoglobin concentration, temperature, ventilatory status, and electrolyte and glucose balance; the duration of the procedures is kept to a minimum. The risk for diagnostic catheterization is less than 0.5%.[19] Fortunately, more serious complications such as chamber or vessel perforation, valve disruption, and embolization related to any invasive procedure are relatively rare, even as the repertoire of neonatal interventional procedures has expanded.

Vascular complications dominate the problems associated with therapeutic procedures in the neonate. The preferred method of vascular access is by the umbilical vein or artery (depending on the lesion) and by percutaneous entry of the femoral vessels, the latter being associated with occlusion of the iliac vein or distal vena cava in 5% to 15% of infants.[68] Arterial trauma is a more pervasive problem in the neonate.

For diagnostic studies, femoral arterial entry is not usually required because the umbilical artery, a ventricular septal defect, or a patent foramen ovale or patent ductus arteriosus allows transcatheter arterial access. However, interventional manipulations are often difficult through these circuitous routes, and direct femoral arterial cannulations might be required. The introduction of small French catheters and low-profile balloons for many of the procedures has reduced the incidence of thrombosis. Vessel recannulation has been demonstrated with the use of heparin and, if necessary, fibrinolytic therapy.[37]

Fetal Interventional Catheterization

See also Chapter 11.

The practice of pediatric cardiology and cardiovascular surgery has advanced significantly with respect to the ability to perform neonatal catheterization interventions and surgical repairs. An extension of this progress is to perform these techniques during fetal life.[36] Establishing normal blood-flow patterns in the fetus who has critical valve stenosis or atresia can allow for more normal growth of vessels and ventricles with the potential for longer postnatal survival and better quality of life. To date, this has primarily focused on the fetuses at risk for ultimate evolution of hypoplastic left heart syndrome and relief of severe semilunar valve stenosis or restrictive atrial septum.[44]

Any form of fetal intervention for cardiovascular disease requires extensive understanding of the fetal pathophysiologic responses to intervention. Research is ongoing to attempt to perform direct surgical corrective and palliative procedures, fetal cardiac bypass, and catheterization interventions. The advancement of technical aspects of such interventions is promising; however, moral and ethical issues and the allocation of medical resources remain key determinants of further progress in the management of the fetus with congenital heart disease.

CHAPTER 46

The Blood and Hematopoietic System

PART 1

Hematologic Problems in the Fetus and Neonate

Lori Luchtman-Jones and David B. Wilson

HEMATOPOIETIC DEVELOPMENT

Hematopoietic Stem Cells

All blood cells are derived from hematopoietic stem cells that originate in differentiating mesoderm.[63] These stem cells are found both in hematopoietic organs (yolk sac, liver, and bone marrow) and in the circulating blood of the embryo, fetus, and infant. Hematopoietic stem cells are pluripotential; each of these cells can give rise to different types of committed progenitors (Fig. 46-1). Like other stem cells of the body, hematopoietic stem cells are capable of self-renewal. At any given time, most hematopoietic stem cells are not cycling but rather are in a resting state. This property, together with a knowledge of surface markers found on these cells (e.g., CD34), has been exploited to isolate highly purified populations of human stem cells. Proliferation and differentiation of stem cells require the proper microenvironment, including supporting adventitial cells and humoral factors. The anatomic sites of hematopoiesis, the nature of the supporting cells, and the growth factors that influence stem cell differentiation change during development.[63]

ANATOMIC AND FUNCTIONAL SHIFTS IN HEMATOPOIESIS

As in other vertebrates, hematopoiesis in the human embryo begins in the yolk sac. Embryonic red blood cells (RBCs) are visible in the yolk sac as early as 2 weeks' gestation.[63] Before the chorioallantoic placenta forms, the yolk sac is solely responsible for uptake and delivery of nutrients and oxygen to the growing embryo; thus, it is not surprising that this organ is the first site of hematopoiesis in the embryo. Hematopoiesis in the yolk sac is restricted to production of RBCs and macrophages. Other types of blood cells (e.g., neutrophils, platelets, and lymphocytes) are not generated in the yolk sac, implying that these latter cell types are not essential for early development. The red blood cells produced by the yolk sac are extremely large (mean corpuscular volume [MCV] = 200) and remain nucleated throughout their brief life span. These cells express embryonic hemoglobins and distinctive surface markers. The metabolic characteristics of yolk sac erythroblasts also differ from those of erythrocytes produced later in development. Studies on chicken and mouse embryos suggest that yolk sac endoderm cells support hematopoietic stem cell differentiation during embryonic development. The humoral or cell-associated factors that regulate yolk sac hematopoiesis are unknown but probably differ from those that control later stages of hematopoiesis, such as erythropoietin or stem cell factor.[42]

At 6 weeks' gestation, the liver becomes the major site of hematopoiesis.[63] Most cells produced during the hepatic stage of hematopoiesis are erythroid, although platelets, neutrophils, and other blood cells also are generated. Between the third and fifth month of life, as many as 50% of the cells within the liver are erythroid precursors. The RBCs produced during this stage of hematopoiesis do not remain nucleated and are smaller than those produced by the yolk sac. During liver hematopoiesis, fetal hemoglobins are the predominant hemoglobins synthesized. The metabolic parameters and surface antigens of these cells differ from yolk sac erythroblasts. Hepatocytes appear to function as support cells for stem cell differentiation during this stage of hematopoiesis. Erythropoietin, possibly derived from extrarenal sources, and other growth factors appear to be required for this stage of hematopoiesis.[42]

By 24 weeks' gestation and after birth, the bone marrow is the principal site of blood cell production.[1] All types of blood cells are generated during marrow hematopoiesis. Beginning in late gestation and continuing through the first year of life, a gradual shift occurs from production of fetal hemoglobins to the so-called adult hemoglobins (see later). Over this period, the MCV of the RBCs continues to decline. Bone marrow stromal cells function as essential support cells during the marrow

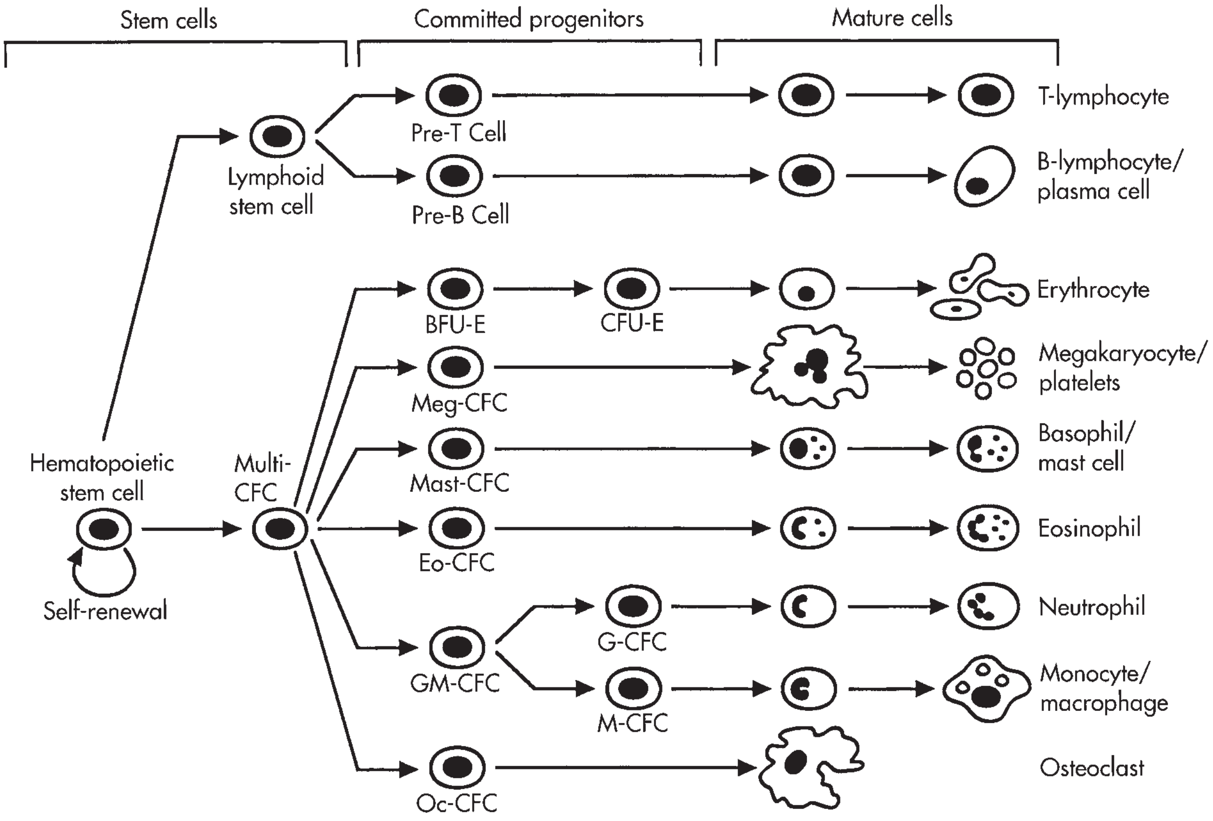

Figure 46–1. Hematopoietic stem cell differentiation. BFU-Ee, burst-forming units, erythroid; CFC, colony-forming cells; CFU-E, colony-forming unit, erythroid; Eo-CFC, eosinophil colony-forming cells; G-CFC, granulocyte colony-forming cells; GM-CFC, granulocyte-macrophage colony-forming cells; M-CFC, macrophage colony-forming cells; Meg-CFC, megakaryocyte colony-forming cells; Oc-CFC, osteoclast colony-forming cells.

phase of hematopoietic development. Bone marrow hematopoiesis depends on a number of growth factors, including erythropoietin and stem cell factor. Erythropoietin levels rise with gestational age, and by birth they exceed adult levels.[42]

Hematopoietic Growth Factors

Growth factors regulate the proliferation, differentiation, and survival of hematopoietic stem cells and committed progenitor cells.[42] In some instances, these factors also influence the survival and function of fully differentiated cells, including nonhematopoietic cells such as endothelial cells. Some hematopoietic growth factors are synthesized by support cells in the vicinity of hematopoietic progenitors, whereas other growth factors are synthesized at more distant sites. The past decade has witnessed a dramatic increase in our understanding of hematopoietic growth factors. Table 46-1 lists the currently known hematopoietic growth factors and their functions. To date, only a few of the glycoprotein growth factors are widely used clinically, although this number is likely to increase in the coming years.

The nomenclature associated with growth factors is complex. Many of these proteins have several names, reflecting the diversity of effects elicited by these factors in vitro and in vivo. For example, stem cell factor (SCF) is also known as kit ligand (KL), mast cell growth factor (M-CGF), and steel factor (SF). Some of the first hematopoietic growth factors identified were called colony-stimulating factors (CSFs), based on in vitro observations that these factors stimulate progenitor cells to form colonies of recognizable maturing cells. In the CSF nomenclature system, prefixes denote the cell types seen in the maturing colonies (e.g., GM-CSF, granulocyte-macrophage CSF). Another group of factors, the interleukins (ILs), were named for their cellular source or action on leukocytes. Still other factors derived their names from the cell surface receptor to which they bind because the receptor was identified before the ligand was characterized (e.g., kit ligand). Some hematopoietic growth factors, such as IL-3 and GM-CSF, support proliferation, differentiation, and survival of a broad range of precursors, including stem cells. Other growth factors, such as erythropoietin and granulocyte CSF (G-CSF), are lineage restricted. Clinical uses for the various hematopoietic growth factors are discussed later in the context of specific hematologic conditions.

RED BLOOD CELLS

Hemoglobins and Oxygen-Carrying Capacity

The function of RBCs is to transport oxygen (O_2) to tissues to meet metabolic demands. Hemoglobin (Hb), the most abundant protein in erythrocytes, facilitates oxygen delivery

TABLE 46–1 Hematopoietic Growth Factors

Factor	Source	Receptor	Target Cells	Effects
Erythropoietin (EPO)	Kidney, hepatocytes	EPO-R	E, Meg	Stimulates growth and differentiation of erythroid precursors
Stem cell factor (SCF) (also known as steel factor [SF], KIT ligand [KL], and mast cell growth factor [MCGF])	Ubiquitous	KIT	E, mast cells, melanocytes, germ cells	Stimulates growth and differentiation of erythroid and myeloid precursors; enhances growth of mast cells
Granulocyte colony-stimulating factor (G-CSF)	Stromal cells, macrophages	G-CSF-R	N	Stimulates growth and differentiation of neutrophil precursors; activates phagocytic function of mature neutrophils
Granulocyte-macrophage colony-stimulating factor (GM-CSF)	Stromal cells	GM-CSF-R (α and β chains)	M, N, Eo, Endo	Stimulates growth and differentiation of neutrophils, eosinophils, and monocytes; activates endothelial cells; induces cytokine expression by monocytes
Macrophage colony-stimulating factor (M-CSF)	Mesenchymal cells	FMS	M	Stimulates growth and differentiation of monocytes; induces phagocytic function in monocytes and macrophages; is involved in bone remodeling
Interleukin 1 (IL-1)	Ubiquitous	IL-1RI, IL-1RII	T, E, B, M, S	Induces production of cytokines and prostaglandins by stromal cells, T cells, and many other cell types; induces fever
Interleukin 2 (IL-2)	T cells	P55, P75	B, T, NK	Induces proliferation and activation of T, B, and NK cells; induces IL-1 expression by monocytes
Interleukin 3 (IL-3)	T cells	IL-3Rα, GM-CSF-Rβ	M, N, Eo, Meg	Stimulates growth and differentiation of myeloid and erythroid precursors, induces cytokines
Interleukin 4 (IL-4)	T cells, mast cells, basophils	IL-4R	M, Ba, B, T	Induces proliferation and activation of B and T cells
Interleukin 6 (IL-6)	Ubiquitous	IL-6R/ GP130	B, N	Induces activation of neutrophils; induces B cell maturation, synergistic with IL-3
Interleukin 7 (IL-7)	Stromal cells	IL-2R	B, T, meg	Stimulates T cells; induces monocytes
Interleukin 8 (IL-8)	Stromal cells, macrophages, T cells	IL-8R	T, N	Induces neutrophils and chemotaxis
Interleukin 10 (IL-10)	T cells, macrophages	IL-10R	Meg, E	Induces B and mast cells; inhibits T cells
Interleukin 11 (IL-11)	Stromal cells	IL-11R, GP130	Meg	Stimulates megakaryocytes
Interleukin 12 (IL-12)	Neutrophils, monocytes	IL-12R	T, NK	Induces differentiation of cytotoxic T cells
Thrombopoietin (TPO)	Unknown	MPL	Meg	Stimulates megakaryocytes

B, B cells; Ba, basophil; E, erythroid precursors; Endo, endothelial cell; Eo, eosinophil; Meg, megakaryocyte; M, monocyte; N, neutrophil; NK, natural killer cell; S, stroma cell; T, T cell.

TABLE 46–2 Human Hemoglobins Expressed During Development

Hemoglobin (Hb)	Globin Chain Composition	Stage of Expression	Primary Site of Production
Hb Gower 1	$\zeta_2\epsilon_2$	Embryonic	Yolk sac
Hb Gower 2	$\alpha_2\epsilon_2$	Embryonic	Yolk sac
Hb Portland	$\zeta_2\gamma_2$	Embryonic	Yolk sac
Hb F	$\alpha_2{}^A\gamma_2$ or $\alpha_2{}^G\gamma_2$	Fetal	Liver
Hb A_2	$\alpha_2\delta_2$	Adult	Bone marrow
Hb A	$\alpha_2\beta_2$	Adult	Bone marrow

by reversibly binding O_2 molecules. Individual molecules of hemoglobin are composed of four globin chains, each of which is covalently bound to a heme prosthetic group. Different globin chains are expressed in the course of normal development (Table 46-2) and in certain pathologic states. The physiologic hemoglobins are tetramers consisting of two α-type globins (α-globin or ζ-globin) and two β-type globins (β-globin, ϵ-globin, $^A\gamma$-globin, $^G\gamma$-globin, or δ-globin). For example, the major adult hemoglobin, Hb A, is composed of two α-globin chains and two β-globin chains ($\alpha_2\beta_2$). In states of globin synthetic imbalance (e.g., the thalassemias), Hb molecules composed of four identical chains can be formed, such as Hb Barts (γ_4) or Hb H (β_4). The binding of oxygen to hemoglobin tetramers is cooperative, resulting in the familiar sigmoidal oxygen dissociation curve (Fig. 46-2). The affinity of Hb molecules for oxygen is influenced by a variety of factors, including temperature, pH, carbon dioxide pressure (P_{CO_2}), and the concentration of red cell organic phosphates (e.g., 2,3-diphosphoglycerate [2,3-DPG]). In the case of Hb A, oxygen affinity for the molecule varies directly with pH and inversely with temperature and the concentration of 2,3-DPG. A high content of fetal hemoglobin (Hb F) is associated with high oxygen affinity, as is explained later (see also Chapter 44).

In the transition from yolk sac to liver to marrow hematopoiesis, different globin genes are sequentially expressed in RBC precursors, a process known as *hemoglobin switching* (Fig. 46-3). The two α-type globin genes, α-globin and ζ-globin, are adjacent on chromosome 16 and are arranged with the ζ gene 5′ to a pair of duplicated α-globin genes. The β-type genes are located on chromosome 11 and are oriented 5′ to 3′ as ϵ-, $^A\gamma$-, $^G\gamma$-, δ-, and β-globin genes. The protein products of the $^A\gamma$- and $^G\gamma$-globin genes differ only at a single amino acid residue and are functionally indistinguishable. During development, α-type and β-type globin gene clusters are activated sequentially from the 5′ (embryonic) end to the 3′ (adult) end. The mechanisms that control globin switching are complex. Temporal and cell-specific expression of specific globin genes is influenced by cis-elements within individual globin gene promoters, a distant 5′-enhancer called the *locus control region*, and a host of positively acting transcription factors, such as GATA1, GATA2, NFE2, MYB, EKLF, RBTN2, and SCL. Other mechanisms that also regulate globin switching are silencers, DNA conformational changes, and DNA methylation.[63]

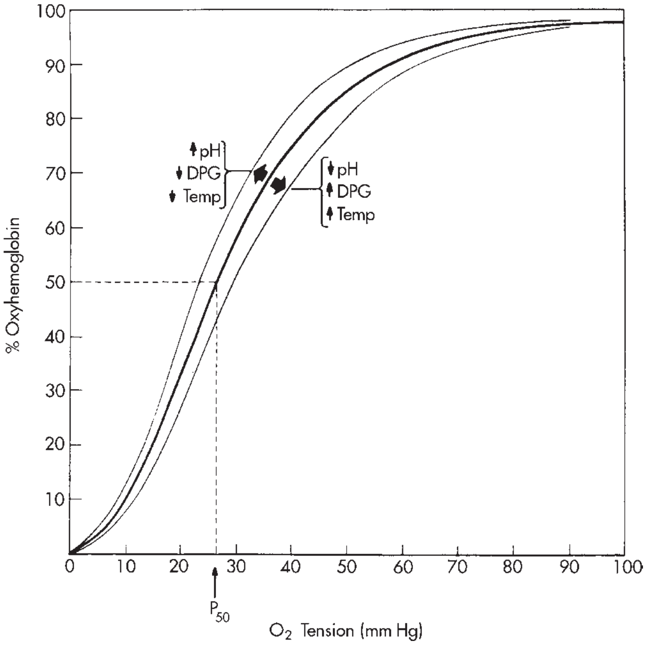

Figure 46–2. Oxyhemoglobin dissociation curve. Factors that influence the position of the curve are indicated. DPG, diphosphoglycerate. (*Adapted from Bunn HF, et al:* Hemoglobin: molecular, genetic, and clinical aspects, *Philadelphia, 1969, Saunders.)*

During yolk sac hematopoiesis, RBCs produce the embryonic hemoglobins (Hb Gower 1 [$\zeta_2\epsilon_2$]; Hb Gower 2 [$\alpha_2\epsilon_2$]; and Hb Portland [$\zeta_2\gamma_2$]). Hb F ($\alpha_2\gamma_2$), the predominant hemoglobin of the fetus and newborn, contains two α chains and two γ chains ($^A\gamma$ or $^G\gamma$, or both). Production of the major adult hemoglobin (Hb A) increases significantly between birth and 6 months of age, commensurate with a decline in the synthesis of Hb F. Synthesis of Hb A_2, a minor adult globin, also increases gradually over the first months of life. In anyone older than 6 months of age, Hb F usually constitutes less than 1% of the total hemoglobin and is unevenly distributed among red blood cells. Normally, only 0.1% to 7% of RBCs contain detectable Hb F. In the cells that express Hb F (F cells), Hb F constitutes about 20% of the cell's total hemoglobin.

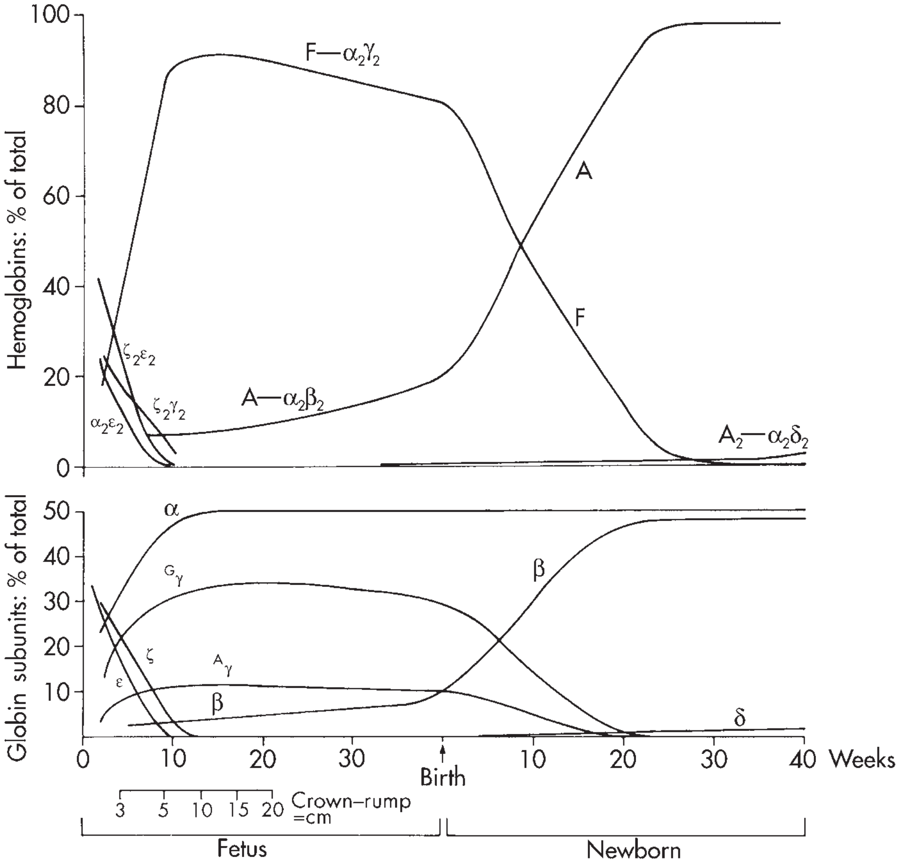

Figure 46–3. Changes in expression of hemoglobin tetramers (*upper panel*) and individual globin chains (*lower panel*) during development. (*Adapted from Bunn HF, et al:* Hemoglobin: molecular, genetic, and clinical aspects, *Philadelphia, 1969, Saunders.)*

The process of hemoglobin switching has been conserved through vertebrate evolution, suggesting that embryonic, fetal, and adult globins serve essential roles in development. Each of these different types of globin exhibits distinctive functional properties. Fetal erythrocytes, which are rich in Hb F, have a considerably higher oxygen affinity than adult red cells. This property is thought to facilitate the transport of oxygen from Hb A-bearing erythrocytes in the maternal circulation across the placenta to fetal red blood cells. The increased O_2 affinity of fetal hemoglobin has been ascribed to the diminished interactions of Hb F with red blood cell organic phosphates. Embryonic erythrocytes also display a greater affinity for oxygen than adult cells.

Erythropoietin Levels and Erythropoiesis

Fetal erythropoiesis is primarily under the control of the fetus. Erythropoietin (EPO) is a glycoprotein produced primarily in the fetal liver as well as in the cortical interstitial cells of the kidney. EPO regulates RBC production in response to tissue oxygen delivery and the oxygen saturation of hemoglobin. Adult erythropoiesis is controlled by the kidney. Levels of EPO in cord blood are higher than in adult blood samples (Table 46-3), but there is a dramatic decrease after birth in response to higher levels of tissue oxygenation. By 1 month of age, serum levels in healthy term infants reach their nadir. This is followed by a rise to maximal levels at 2 months of age, and then a slow drift down to adult values.[27] The postnatal changes in tissue oxygenation and erythropoietin production result in a physiologic anemia of infancy with mean minimal hemoglobin concentrations in healthy term infants of about 11 g/dL at 6 to 9 weeks of life (Fig. 46-4; and see Table 46-5, later). Because of the shorter red blood cell life span in preterm infants, this physiologic anemia of infancy is noted earlier and may be more severe. Other causes of blood loss and suppression of erythropoiesis in the ill neonate can contribute to more severe and earlier anemia. Although preterm infants will respond to hypoxia with a rise in EPO levels, the increase is lower than that expected for term infants. The suboptimal EPO response may be due to developmental changes in transcription factors or to the site of fetal EPO production. The use of recombinant EPO in premature and sick newborn infants is discussed later.

Red Blood Cell Indices during Prenatal and Postnatal Development

The RBC count, Hb concentration, and hematocrit (Hct) increase throughout gestation, as shown in Table 46-4. In term infants, the mean capillary hemoglobin at birth is 19.3 g/dL (Table 46-5). The Hct has a mean of 61 g/dL. Premature infants have lower Hct levels than do full-term infants (see Table 46-4). In addition to gestational age, Hb and Hct levels are influenced by a variety of factors that must be kept in mind when analyzing the neonate with anemia or polycythemia. One important determinant of blood Hct is the site of sampling: capillary hematocrit values are higher than peripheral venous samples, and umbilical venous Hct results are the

TABLE 46–3 Serum Erythropoietin Levels During Infancy

Postnatal Age (days)	Serum Erythropoietin Level (mU/mL)	Sample Size
0-6	33.0 ± 31.4	11
7-50	11.7 ± 3.6	7
51-100	21.1 ± 5.5	13
101-150	15.1 ± 3.9	5
151-200	17.8 ± 6.3	6
>200	23.1 ± 9.7	10

From Yamashita H, et al: Serum erythropoietin levels in term and preterm infants during the first year of life, *Am J Pediatr Hematol Oncol* 16:213, 1994.

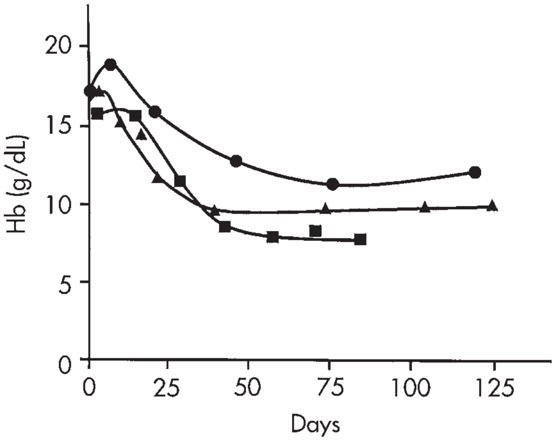

Figure 46–4. Hemoglobin concentrations in full-term and premature infants. (●) Full-term infants; (▲) premature infants, birthweight 1200 to 2350 g; (■) premature infants, birthweight less than 1200 g. (*Adapted from Oski F: The erythrocyte and its disorders. In Nathan D, et al, editors:* Hematology of infancy and childhood, *4th ed, Philadelphia, 1993, Saunders, p 18.*)

lowest. The interval between delivery and clamping of the umbilical cord also can significantly affect a newborn's blood volume and total RBC mass. The placenta contains about 100 mL of blood, and the mean blood volume of a full-term infant is about 85 mL/kg. Early or delayed clamping of the umbilical cord alters this mean blood volume by about 10% lower or higher, respectively. The average Hct at birth is relatively unchanged; however, 48 hours later, after redistribution of plasma volume, Hct values will reflect the lower or higher red cell mass. Racial differences also occur: one study reported significantly higher Hb, Hct, and MCV in white infants compared with black infants of similar gestational ages.[3] Reticulocyte counts in the cord blood of infants average 4% to 5%, and nucleated RBCs are evident in most cord blood samples (40,000/μL). These findings are presumed to reflect high EPO production secondary to low oxygen retention in utero. Infants who experience placental insufficiency and intrauterine growth restriction have higher than normal EPO production and an even greater degree of erythrocytosis. The mean MCV of RBCs in the newborn is increased. The RBCs of the neonate have an increased Hb content, but the mean corpuscular hemoglobin concentration is comparable to that of adults.

Red Blood Cell Survival

The normal life span of adult RBCs is about 120 days. The life span of RBCs in newborns at term is about 60 to 80 days, and it is even more truncated in preterm infants. When the RBC life span is less than 2 standard deviations below the mean for age, hemolysis is occurring. In general, red blood cell survival is affected by changes related to aging (senescence) and by random hemolysis of red blood cells, or portions of red blood cells, in the spleen and the rest of the reticuloendothelial system. Aging erythrocytes with declining RBC enzyme activity become progressively less tolerant of oxidative challenges during the transportation of oxygen molecules and exposure to circulating oxidants. Any additional deficiencies in the enzymatic pathways of the RBC may affect the ability of the erythrocyte to tolerate oxidative challenges and further shrink red blood cell survival. With transit through the kidneys and lungs, the RBCs experience cycles of osmotic swelling and shrinkage. Shear forces in high-pressure areas of the circulation buffet the erythrocytes. Each passage through the cords of Billroth within the spleen requires the RBCs to deform and squeeze through tiny slits in the walls of the cords or face destruction if they cannot. Congenital or acquired defects in membrane stability or decreases in the ratio of surface area to red blood cell volume will also decrease erythrocyte survival. Alterations in the deformability of neonatal erythrocytes and relative intolerance to oxidative challenges result in shorter survival for neonatal red blood cells. Random hemolysis can be increased with splenic enlargement or activation of the phagocytic system. Infants with hemolysis may have exaggerated anemia because of decreased erythropoiesis, enhanced splenic filtration, and activation of phagocytes.

RED BLOOD CELL DISORDERS

Anemia

DEFINITION

Anemia is defined by a hemoglobin or hematocrit value that is more than 2 standard deviations below the mean for age. In the neonate, the causes of anemia can be divided into two broad categories: anemia resulting from accelerated loss or destruction of red blood cells and anemia caused by a defect at some stage of red blood cell production (Box 46-1). The defects may be congenital or acquired, and the abnormality may be intrinsic to the RBCs or extrinsic. Anemias also may be categorized on a morphologic basis. Using the normal range of the MCV for age and gestation, the anemia may be characterized as microcytic, normocytic, or macrocytic (Box 46-2). Hypochromicity, abnormal RBC shapes (poikilocytes), polychromasia, and cell inclusions (e.g., basophilic stippling or Howell-Jolly bodies) also provide clues to the etiology of the anemia (Table 46-6).

TABLE 46–4 Red Blood Cell Values (Arterial Samples) on First Postnatal Day at Different Gestational Ages[*]

Variables	Group 1	Group 2	Group 3
	23-25 wk (n = 40)	*26-28 wk (n = 60)*	*29-31 wk (n = 88)*

BOX 46–1 Anemias by Etiology

ACCELERATED LOSS

Hemorrhage
- Fetal
- Placental
- Traumatic delivery
- Coagulation defect

Early umbilical cord clamping
Twin-twin transfusion
Fetal-maternal transfusion

ACCELERATED DESTRUCTION

Hemolytic anemia
- Immune
    - Alloimmune: Rh, ABO, minor blood group
    - Autoimmune
- Nonimmune
    - Hemoglobinopathy
    - Thalassemias
    - Unstable hemoglobin
    - Red blood cell enzymatic defect
    - Structural defect of red blood cell membrane
    - Mechanical destruction
    - Microangiopathic hemolytic anemia
    - Infection
    - Vitamin E deficiency

DIMINISHED RED BLOOD CELL PRODUCTION

Congenital
- Diamond-Blackfan anemia
- Fanconi anemia
- Anemia of prematurity
- Congenital dyserythropoietic anemia

Acquired
- Parvovirus B19
- Transient erythroblastopenia of childhood
- Human immunodeficiency virus infection
- Syphilis
- Iron deficiency
- Lead toxicity
- Excess phlebotomy losses

BOX 46–2 Classification of the Anemias According to Mean Corpuscular Volume

MACROCYTIC ANEMIA

Reticulocytosis
Folic acid deficiency*
Vitamin B_{12} deficiency*
Organic aciduria, acidemia (orotic aciduria, or MMA)
Diamond-Blackfan anemia
Fanconi anemia
Acquired aplastic anemia
Drugs

MICROCYTIC ANEMIA

Iron deficiency
Lead poisoning
Thalassemia
Chronic infection

NORMOCYTIC ANEMIA

Low reticulocyte count
- Infection
- Parvovirus B19
- Transient erythroblastopenia of childhood
- Chronic disease
- Immune HA
- Mechanical HA
- Drugs
- Leukemia
- Hemoglobinopathy
- Unstable hemoglobin

Normal or high reticulocyte count
- Blood loss
- Sequestration
- Red blood cell enzyme defects

---

*Macro-ovalocytes.
HA, hemolytic anemia; MMA, methylmalonic aciduria.

EVALUATION

The clinician begins the evaluation of anemia by taking a thorough history. Appropriate data vary with the patient's age but often include the medical and dietary history of the pregnancy, the estimated gestational age at birth, the chronologic age, the infant's diet, and details of any previous anemia, blood loss, transfusions, medications, and illnesses, as well as the family history of anemia. The physical examination should evaluate the infant's general health, growth, and development. Identification of any dysmorphic features, abnormal masses, or skin lesions can aid the diagnosis (Table 46-7). The patient also should be assessed for jaundice, hepatosplenomegaly, cardiovascular function, and lymphadenopathy.

The initial laboratory evaluation includes a complete blood count (CBC) with RBC indexes, a reticulocyte count, and evaluation of the peripheral blood smear (Fig. 46-5). The results of the preliminary laboratory testing, combined with information from the history and physical examination, should dictate the need for further tests, such as hemoglobin analysis of the infant or parents, CBCs and blood smears of the parents, analysis of hepatic or renal function, direct or indirect antiglobulin (Coombs) testing, cultures or titers to identify infectious agents, a bone marrow aspirate or biopsy, osmotic fragility tests, and quantitative or qualitative testing for glucose-6-phosphate dehydrogenase (G6PD) deficiency.

The neonatal patient presents the diagnostician with a number of unique challenges. Because of the small total blood volume of the infant, who already is anemic, testing must be limited. Major pediatric medical centers can perform many of the necessary tests on very small quantities of blood, especially if the tests are appropriately batched when they are submitted. Because of the many morphologic and biochemical differences in fetal and infant RBCs, some diagnoses are best made by testing the parents for evidence of disease or carrier states. At times, a definitive diagnosis can be made only with repeat testing later in infancy, when the infant would be expected to have a much higher percentage of adult-type RBCs or when the infant has recovered from an acute hemolytic crisis that might have destroyed the older, more biochemically or morphologically abnormal cells.

TABLE 46–6 Morphologic Findings on Peripheral Blood Smears

Morphologic Finding	Etiologies
Hypochromia	Iron deficiency, thalassemia, lead poisoning
Target cells	HB C, S, or E; thalassemia; liver disease; abetalipoproteinemia
Sickle cells	Hb S disease and variants
Basophilic stippling	Iron deficiency; lead poisoning; hemolytic anemia; thalassemia
Heinz bodies	Normal in newborn; hemolytic anemias—enzymatic defects
Howell-Jolly bodies	Splenic hypofunction or postsplenectomy
Spherocytes	Immune HA ABO more common than Rh; G6PD deficiency; structural defects of red blood cell membrane cytoskeleton
Elliptocytes	Structural defects of red cell membrane cytoskeleton
Schistocytes	Microangiopathic hemolytic anemia
Nucleated red blood cells	Normal in newborn; hemolytic anemia; semi-acute blood loss
Polychromasia	Normal in newborn; proliferative response to anemia

G6PD, glucose-6-phosphate dehydrogenase; HA, hemolytic anemia.

TABLE 46–7 Physical Findings in Neonatal Anemia

Physical Finding	Etiologies
Short stature	Fanconi anemia; Diamond-Blackfan anemia
Microcephaly	Congenital infection
Dysmorphic features	Fanconi anemia; Diamond-Blackfan anemia
Jaundice	Hemolytic anemia
"Blueberry muffin" spots	Congenital infection
Petechiae	Bone marrow infiltration/failure; disseminated intravascular coagulation; sepsis
Congestive heart failure	Chronic anemia causing decompensation
Cardiac disease	"Waring blender" syndrome
Giant hemangioma	Kasabach-Merritt syndrome

RATIONALE FOR TRANSFUSION THERAPY

See also Chapter 46, Part 2.

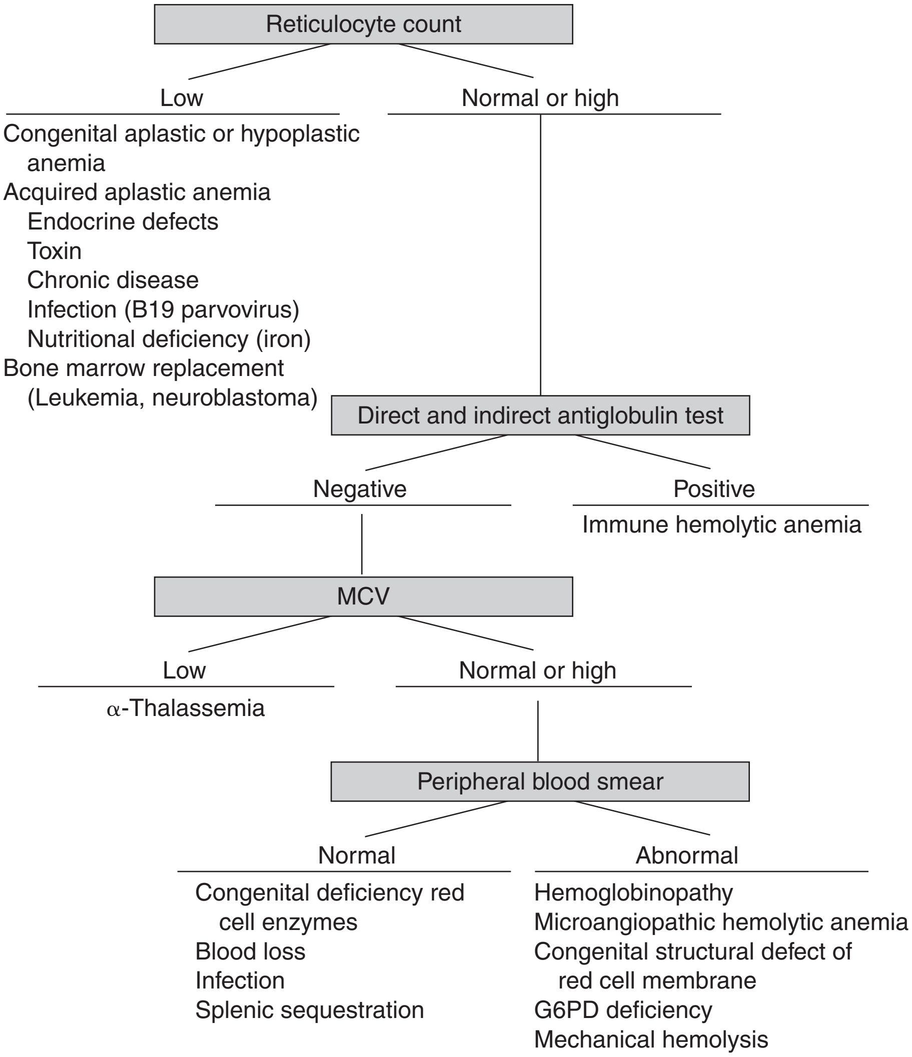
Because the primary function of the RBC is to transport oxygen from the pulmonary bed to other tissues for release, anemia diminishes oxygen-carrying capacity and can compromise tissue oxygenation. Tissue oxygenation is a complex concept involving not only the Hb concentration but also the oxygen affinity of the hemoglobin in the patient's red blood cells and the patient's cardiorespiratory status. The only absolute indications for rapidly correcting anemia by RBC transfusion are to restore tissue oxygenation and to expand blood volume after severe, acute loss. In most pediatric centers, the sicker patients, especially those with cardiopulmonary dysfunction, receive transfusions to maintain the Hb and Hct values closer to normal for that age. Neonatal exchange transfusions are also performed with the goal of replacing "doomed" infant RBCs with healthy adult RBCs, which have superior oxygen-transporting ability. This has the triple benefit of limiting hyperbilirubinemia from RBC breakdown, reducing the body load of maternal antibodies, and supplementing with cells that contain Hb A.

ANEMIA CAUSED BY BLOOD LOSS

Blood loss can occur in the fetus, at birth, or in the postnatal period. The bleeding can be acute or chronic. Anemia caused by chronic blood loss generally is better tolerated because the neonate will at least partly compensate for a gradual reduction in RBC mass. Chronic blood loss can be diagnosed by identifying signs of compensation. Doppler assessment of the fetal middle cerebral artery peak systolic velocity is a noninvasive method for determination of fetal anemia, independent of the etiology. The infant may be pale and might exhibit signs and symptoms of congestive heart failure. Anemia will be present, often with reticulocytosis, hypochromia, and microcytosis.

An infant with acute blood loss may not be anemic if blood sampling is done soon enough after the acute event that hemodilution has not yet occurred. Anemia usually develops within 3 to 4 hours after blood loss; repeat testing 6 to 12 hours after the event should reveal the true extent of the loss. In acute blood loss, the infant might exhibit signs and symptoms of hypovolemia and hypoxemia (e.g., tachycardia, tachypnea, and hypotension). The RBCs should be morphologically normal. With either kind of hemorrhage, infants tend to have fewer problems with hyperbilirubinemia because they have a reduced RBC mass.

Either maternal or fetal factors can cause prenatal blood loss. In a study of 259 patients in a neonatal intensive care unit, Faxelius and colleagues[30] correlated reduced RBC mass with a maternal history of vaginal bleeding, placenta previa, abruptio placentae, nonelective cesarean delivery, and cord compression. Infants with 1-minute Apgar scores of 6 or lower also had a lower RBC volume at birth or shortly thereafter. Hemorrhage from the umbilical cord may be the result of intrinsic vascular abnormalities, inflammation of the cord, velamentous insertion of the cord, or an unusually short cord. A normal cord can rupture during a precipitous or assisted delivery or if it becomes tangled around the infant. Placental abnormalities such as abruptio placentae or placenta



Reticulocyte count
Low
Normal or high
Congenital aplastic or hypoplastic anemia
Acquired aplastic anemia
Endocrine defects
Toxin
Chronic disease
Infection (B19 parvovirus)
Nutritional deficiency (iron)
Bone marrow replacement
(Leukemia, neuroblastoma)
Direct and indirect antiglobulin test
Negative
Positive
Immune hemolytic anemia
MCV
Low
Normal or high
α-Thalassemia
Peripheral blood smear
Normal
Abnormal
Congenital deficiency red cell enzymes
Blood loss
Infection
Splenic sequestration
Hemoglobinopathy
Microangiopathic hemolytic anemia
Congenital structural defect of red cell membrane
G6PD deficiency
Mechanical hemolysis

Figure 46–5. Algorithm for diagnosis of anemia in the neonate. MCV, mean corpuscular volume.

previa can cause hemorrhage. Accidental incision of the placenta during delivery also can result in bleeding.

The acid elution technique, or Kleihauer-Betke test, can be used to look for fetal RBCs in vaginal or peripheral blood samples from women with vaginal bleeding late in pregnancy. This method exploits the stability of Hb F-containing RBCs in acid solution relative to cells containing Hb A. False-positive test results are seen in women with any condition, including many of the hemoglobinopathies, that elevates their own Hb F level. Some centers now offer immunofluorescence flow cytometry testing, which can sort RBCs by whether they are Rh negative or positive. This is useful for evaluating the amount of Rh positive fetal blood that is present in a blood sample from an Rh negative mother.[33]

Fetal-Maternal Hemorrhage

Fetal cells may be found in the maternal circulation in about half of all pregnancies. In about 8% of pregnancies, the transfer of blood is estimated to be between 0.5 and 40 mL; in about 1% of pregnancies, the volume of blood transferred exceeds 40 mL.[33] Fetal-maternal hemorrhage is more common after procedures such as an external cephalic version before delivery or a traumatic amniocentesis. The diagnosis is made by demonstrating fetal RBCs in a maternal blood sample; therefore, the analysis must be done before the fetal cells are cleared from the maternal circulation. The test usually is performed within the first few hours after delivery; in cases of ABO blood group incompatibility, the red cells may be cleared faster than this, and the test may be falsely negative. The most commonly performed test is the Kleihauer-Betke test, although flow cytometry is available in many major centers. If the maternal Hb F level is above normal, another type of test that is based on differential agglutination should be used.

TWIN-TWIN TRANSFUSION

In monozygotic multiple births with monochorial placentas, blood can be exchanged between the fetuses through vascular anomalies (see Chapters 19 and 24). The incidence of twin-twin transfusions has been estimated at 9% to 15% of monochorionic pregnancies and can be associated with a high risk for fetal and neonatal morbidity and mortality. Transfusion can be problematic for the hypovolemic donor who develops oligohydramnios, but the recipient often experiences greater difficulties with hyperbilirubinemia, hypervolemia, and hyperviscosity that arise from the increased RBC mass. Cardiac, neurologic, and developmental disorders have been associated with twin-twin transfusion syndrome.[66]

HEMORRHAGE

Internal bleeding can occur if the fetus has anatomic abnormalities or defects in the hemostatic system, or with a history of interventional obstetric procedures. Often the first signs of internal hemorrhage in the newborn are those of hypovolemic shock and hypoxemia. Jaundice occurs later when the entrapped RBCs break down. A surprisingly large amount of blood can be lost within a cephalohematoma (see Chapter 28), and even greater bleeding can occur in the subaponeurotic area of the scalp (subgaleal hemorrhage), where bleeding is not limited by periosteal attachments. Traumatic or assisted deliveries and vitamin K deficiency are commonly associated with such bleeding. Full-term infants might have intracranial bleeding, which usually occurs in the subarachnoid or subdural regions (see Chapter 40). Although the cause might not be found, full-term infants with intracranial hemorrhage should be evaluated for hemostasis abnormalities because this type of bleeding is associated with qualitative and quantitative platelet defects and with abnormalities of several of the coagulation proteins. Hemorrhage into the adrenals, kidneys, liver, spleen, or retroperitoneum also can occur after difficult or breech deliveries. Splenic or hepatic rupture can occur after trauma, especially if the organs are enlarged as a result of extramedullary hematopoiesis. Occult or superficial vascular tumors can bleed and sequester large volumes of red blood cells and platelets.

HEMOLYTIC ANEMIA: ACCELERATED DESTRUCTION OF RED BLOOD CELLS

See also "Red Blood Cell Survival."

Accelerated destruction of RBCs is the endpoint of a number of intrinsic, extrinsic, congenital, and acquired RBC abnormalities. Because the RBCs of premature infants and newborns have a shorter life span, *hemolysis* is defined as a process that shortens the survival of the RBCs relative to the life span expected for the infant's gestational and postnatal age. In contrast to anemia caused by blood loss, most infants with hemolysis have some evidence of indirect hyperbilirubinemia and elevated lactate dehydrogenase for age. Reticulocytosis should accompany the hemolysis, although in conditions complicated by bone marrow suppression (e.g., congenital infections, chronic illness, or nutritional deficiency) or decreased EPO production, the reticulocyte count may be inappropriately low for the degree of anemia present. With maximal bone marrow response, RBC survival of 20 to 30 days can be compensated for without anemia. The bone marrow may show hyperplasia and a reversal of the usual myeloid-to-erythroid ratio of 3:1. Because optimal conditions for bone marrow response are not present in the newborn, hemolysis with anemia and hyperbilirubinemia may be evident in the neonate. In chronic hemolytic states, compensatory hypertrophy of the bone marrow may result in bony changes over time, especially of the skull and hands.

Intrinsic hemolytic anemias are caused by inherited abnormalities of the RBC membrane, hemoglobin, or RBC intracellular enzymes. Extrinsic factors cause hemolytic anemia by damaging the RBC chemically, physically, or immunologically. Some intrinsic hemolytic anemias also result in extrinsic damage to RBCs. Extrinsic hemolysis can be divided into immune and nonimmune etiologies (Table 46-8); the most common causes of immune hemolytic disease are discussed first.

ALLOIMMUNE HEMOLYTIC ANEMIA

See Chapter 21.

Alloimmune hemolytic disease of the newborn (HDN) is caused by the destruction of fetal or neonatal RBCs by maternal immunoglobulin G (IgG) antibodies. Alloimmune HDN involves the major blood group antigens of the Rhesus (Rh),

TABLE 46–8 Acute Hemolytic Anemia: Causative Mechanisms and Representative Infectious Agents

Mechanism	Infectious Agent
Release of hemolysin	*Clostridium perfringens*
Direct invasion of red blood cell	Malaria
Alteration of red blood cell surface	
By adherence of organism	*Bartonella* organisms
By alteration of antigenic phenotype by neuramidase	Influenza virus
By cold agglutinin	Epstein-Barr virus
By absorption of capsular polysaccharide	*Haemophilus influenzae*
Microangiopathy	Any agent causing disseminated intravascular coagulation or hemolytic-uremic syndrome
Enhanced oxidative damage in patients with enzyme deficiency	*Campylobacter jejuni* enteritis in neonates with a diminished cytochrome-b_5 reductase system

A, B, AB, and O systems, but minor blood group incompatibilities (Kell, Duffy, MNS, and P systems) can also be associated with clinically significant disease. Particularly for Rh (D), anti-c, anti-E, and anti-K (Kell) antibodies, intrauterine or direct fetal transfusion may be indicated prenatally, and exchange transfusion may be necessary postnatally. Maternal IgG antibodies can cross the placenta, enter the fetal circulation, and cause hemolysis, anemia, hyperbilirubinemia, and hydrops fetalis. In utero, the process is called *erythroblastosis fetalis*, while postnatally it is called hemolytic disease of the newborn (HDN). Maternal sensitization occurs through a prior transfusion of incompatible RBCs, after fetal-maternal hemorrhage of incompatible fetal RBCs, or from production of a preexisting antibody developed against antigens from bacteria, viruses, or food. Transfer of antibodies across the placenta depends on the F_c component of the IgG molecule. Because both IgM and IgA antibodies lack this component, only IgG antibodies cause hemolytic disease of the newborn. IgG1 antibodies cross the placenta earlier and are responsible for more prenatal hemolysis. IgG3 antibodies cross the placenta later in gestation and are responsible for more severe hemolysis postnatally.

Rh Hemolytic Disease

The original description of HDN was due to Rh (D) incompatibility, and it remains the most severe cause. The spectrum of clinical problems caused by Rh HDN ranges from mild, self-limited hemolytic anemia to hydrops fetalis. With the widespread use of antenatal and postpartum Rh immunoglobulin administration, Rh(D) sensitization is less common in pregnancies in which prenatal care is received. Failure to administer Rh immunoglobulin when indicated, nonrecognition of a large fetal bleed, and chronic transplacental hemorrhage account for most of the cases currently seen.

The Rh antigens are inherited as a linked group of two genes, *RHD* and *RHCE*, located on chromosome 1. People are typed as Rh negative or positive based on the expression of the major D antigen on the RBC, and their RBCs will also express C or c and E or e antigens. Rarely, Rh deletions of D, C/c, and E/e loci can occur. Anti-c and anti-E are emerging as the most frequent causes of isoimmune HDN as the incidence of Rh(D) disease decreases. The incidence of Rh disease depends on the prevalence of Rh-negative antigens in the population studied (Table 46-9). Even in white populations, only a small percentage of pregnancies are affected because not all women who are Rh negative develop antibodies, Rh immunization of the mother does not usually occur during the first pregnancy, and some of the second infants will be Rh negative.

TABLE 46–9 Prevalence of Rh-Negative Genotype (CDE/CDE) by Population

Population Group	Percent Affected
European whites	11-21
U.S. whites	14.4
Indians (India)	8
U.S. African Americans	5.5
Native Americans	0
Chinese	0
Japanese	0

Adapted from Prokop O, et al: *Human blood and serum groups,* Barking, UK, 1969, Elsevier.

The interaction of the anti-D IgG with a D-positive RBC does not usually involve complement. Hemolysis generally is extravascular. Hyperbilirubinemia and jaundice can occur in the first day of life because the placenta no longer is available to clear bilirubin from hemolyzed RBCs. The peripheral blood smear might show anemia, reticulocytosis, and macrocytosis. Microspherocytes are usually not seen in Rh disease. A direct antiglobulin (Coombs) test should demonstrate anti-D IgG. Partial or total exchange transfusions may be necessary to reduce the load of antibody and remove the antibody-coated cells. Management of hyperbilirubinemia is discussed in Chapter 48. In a series of 101 babies born to Rh(D)-negative mothers who received one or two doses of anti-D immunoglobulin, no signs of hemolysis were noted in the Rh(D)-positive or Rh(D)-negative infants. Twenty percent of Rh-positive babies whose mothers received two doses of anti-D immunoglobulin had a positive direct Coombs test, compared with 2.4% of those whose mothers received only one dose.[49]

ABO Hemolytic Disease

Although the incidence of blood group O mothers delivering babies of blood group A or B is about 15%, ABO hemolytic disease is estimated to occur in only 3% of pregnancies and requires treatment with exchange transfusion in less than 0.1% of pregnancies. In contrast to Rh hemolytic disease, ABO hemolytic disease tends to be less severe (i.e., less frequently requires exchange transfusion), and the severity does not depend on birth order. Maternal anti-A or anti-B IgG antibodies, which might have been raised against A or B substances occurring in food or on bacteria, can cross the placenta and react with the sparsely distributed A or B antigens on the neonatal RBCs. ABO HDN occurs in infants with type A or B blood. African-American infants with type B blood can have more severe hemolysis, presumably because the B antigen is more developed in this group of neonates.

Hemolysis is primarily extravascular. Infants may develop anemia, reticulocytosis, and hyperbilirubinemia within the first 24 hours of life. The hallmark of ABO hemolytic disease (in contrast to Rh disease) is the presence of microspherocytes on the peripheral blood smear. The direct antiglobulin test should be at least weakly positive for anti-A or anti-B; however, because of the sparse distribution of antigenic sites on a newborn's RBCs, ABO hemolytic disease may be present even without a positive result on the direct antiglobulin test. The maternal serum should have high titers of IgG directed against A or B (positive indirect antiglobulin test). In the absence of clinical hemolytic disease, laboratory evidence of erythrocyte sensitization should not be considered HDN.

Minor Blood Group Hemolytic Diseases

The incidence of HDN for minor blood group antigens is related to the antigenicity of the particular blood group antigen and the expression of that antigen on fetal RBCs. Maternal antibodies against minor blood group antigens develop after exposure from a transfusion or prior pregnancy, or from contact with bacteria or viruses that express the antigen. HDN has been associated with the minor group antigens Kell, Duffy, MNS system, and P system. Most clinically significant HDN not attributed to ABO or Rh incompatibility is due to anti-Kell, anti-E, and anti-c. Kell HDN may require intrauterine intervention. The severity of anti-Kell HDN is due both to hemolysis and to suppression of erythropoiesis in progenitor cells. Screening for minor group antibodies is recommended for all women in the 34th week of pregnancy: routine screening with cells containing only high-frequency antigens would not detect antibodies to low-frequency antigens. The diagnosis and treatment of hemolytic disease are identical to those for Rh hemolytic disease (see Chapters 21 and 48). Identification of low-frequency antibodies associated with HDN is especially important for mothers who plan additional pregnancies.

Natural History of Hemolytic Diseases of the Newborn

Hydrops fetalis is the most severe consequence of hemolysis, but anemia generally is less problematic than hyperbilirubinemia in the acute phase of illness. Hyperbilirubinemia may be evident within the first 24 hours of life. Anemia can occur in the first few weeks in both those who received exchange transfusions and those who required only phototherapy for management of hyperbilirubinemia. Many causes for the anemia have been postulated, including ongoing destruction of native cells by anti-blood group IgG, hypersplenism, inadequate replacement by transfused red blood cells, and shortened survival of transfused red blood cells. Because the half-life of IgG molecules is about 28 days, hemolysis should resolve within the first 3 or 4 months. Resolution often occurs sooner if the antibodies are cleared by adhering to RBCs or by exchange transfusion. Thrombocytopenia and bleeding can complicate hemolytic disease. Usually thrombocytopenia, without other laboratory evidence of disseminated intravascular coagulation (DIC), is noted, but DIC can be triggered by massive hemolysis or shock and acidosis.

Other Immune Hemolytic Anemias

The other immune hemolytic diseases of early childhood are relatively rare. Autoimmune hemolytic anemia occurs, as do anemias associated with infections, drugs, and immunodeficiency syndromes. IgG antibodies, with or without complement, are often directed against one of the Rh erythrocyte antigens. These antibodies are most active at 37°C and often are called *warm autoantibodies*. The IgG-coated cells, with or without the assistance of complement, are cleared by the spleen and, to a lesser extent, by the liver. Congenital infections (syphilis, cytomegalovirus [CMV], rubella, toxoplasmosis, herpes), bacterial infections, and viral infections, such as infection with the human immunodeficiency virus (HIV) and hepatitis, can cause hemolytic anemia and bone marrow suppression with reticulocytopenia (see Chapter 39). IgM autoantibodies can cause disease and usually are referred to as *cold agglutinins* because they are most active at between 0° and 30°C. These antibodies, with complement, coat RBCs and are usually cleared in the liver. Intravascular hemolysis is less common. The best known causes of cold hemagglutinin disease are *Mycoplasma pneumoniae* and Epstein-Barr virus. IgA-mediated hemolysis is quite rare but is remarkable for its severity.

The natural history of autoimmune hemolytic disease in infancy is that of a rapid onset of anemia with hyperbilirubinemia, splenomegaly or hepatomegaly, and hemoglobinuria. Initially, reticulocytopenia may be noted, especially if antibodies are directed against RBC progenitors in the bone marrow, but a brisk reticulocytosis usually follows. Resolution within 3 to 6 months is common. Anemia with reticulocytosis and spherocytosis may be seen on the peripheral blood smear, but the diagnosis depends on demonstration of antibody-coated cells, with or without complement, in the direct and indirect antiglobulin tests. Therapy includes treatment of underlying infection, removal of the offending drug, and supportive measures to limit hyperbilirubinemia. Response to corticosteroids is common, as is complete recovery. Steroids are less effective in IgM-mediated disease. A subset of patients younger than 2 years and with a slower onset of disease at presentation develop chronic hemolytic anemia. Difficulties with identifying compatible blood during a hemolytic crisis, as well as the usually self-limited nature of the disease, restrict blood transfusions to cases in which severe anemia impairs tissue oxygenation.

NONIMMUNE HEMOLYTIC ANEMIA

Erythrocyte Structural Defects

During its lifetime, a normal RBC traverses the circulation thousands of times, enduring tremendous mechanical and metabolic stress with each passage. The smallest capillaries have an internal diameter that is smaller than the diameter of the RBC; thus the blood cells must deform to squeeze through the capillaries and then return to their normal shape as they enter distal venules. During their rapid transit, the RBCs must endure tremendous fluctuations in pH, P_{O_2}, and osmotic pressure. The lipid bilayer that forms the cell membrane is the site of numerous biologic functions mediated by integral proteins. It also is the attachment site for the proteins of the cytoskeleton, which confer the shape and stability necessary for proper membrane function. Some abnormalities in the membrane-cytoskeleton unit result in morphologic defects of RBCs (Fig. 46-6).[34] Because abnormally shaped RBCs are removed from the circulation by the reticuloendothelial system, many of these defects cause some degree of hemolytic anemia. Analysis of these defects has led to an understanding of the erythrocyte membrane and cytoskeleton.

The more common erythrocyte cytoskeletal defects originally were described by morphologic, genetic, and clinical criteria. As knowledge of the cytoskeleton at a molecular level accumulated, it became clear that various mutations in genes coding for a few structural proteins were responsible for a family of inherited hemolytic anemias with overlapping morphologic, clinical, and genetic features. Mutations in the genes encoding α-spectrin, β-spectrin, ankyrin, protein 4.1, glycophorin C, protein 4.2, and band 3 all have been reported in patients with hereditary spherocytosis, hereditary elliptocytosis, hereditary ovalocytosis, and hereditary pyropoikilocytosis.[34]

The following discussion of the most common disorders uses the classic morphologic criteria. These defects commonly manifest during childhood and occasionally cause hepatosplenomegaly, hyperbilirubinemia, and hemolytic

Vertical interactions are those needed to stabilize the attachment of the spectrin lattice to the lipid bilayer. Abnormalities in this attachment result in destabilization of the lipid bilayer, membrane loss during splenic conditioning, and HS. Horizontal interactions reversibly hold spectrin dimers and tetramers together, allowing stretching and distortion of the red blood cell membrane during circulation. Weakening of these interactions results in loss of elasticity. GP, glycoproteins. (*Adapted from Palek J: Red cell membrane disorders. In Hoffman R, et al, editor:* Hematology: basic principles and practice, *New York, 1991, Churchill Livingstone, p 472.)*

anemia in the neonate. Often the specific diagnosis depends on evaluation of family members and serial examinations of the infant's blood smear over time. Aplastic crisis, attributed to drugs or an infectious agent such as parvovirus B19, or splenic sequestration might cause life-threatening anemia in patients with hemolytic anemia. The more severe cases of hemolytic anemia can require splenectomy, although surgery generally is delayed beyond the first few years of life.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis is characterized by the appearance of spherocytes on the peripheral blood smear, accompanied by a hemolytic anemia of varying severity and by splenomegaly. Hereditary spherocytosis is noted predominantly in those of Northern European ancestry. Inheritance usually is autosomal dominant, but autosomal recessive inheritance and autosomal dominant inheritance with reduced penetrance also have been reported.[11] The defects studied alter the stability of the cytoskeleton attachment to the lipid bilayer, so that pieces of membrane are removed in the spleen. Defect or deficiency in spectrin are the most common, with some accompanying defects in ankyrin, band 3, and protein 4.2.[34] Nondeformable spherocytes with a decrease in the surface area are more susceptible to lysis on exposure to the metabolic and deformation stresses of the splenic sinuses or with incubation in hypo-osmolar solutions. The osmotic fragility test exposes the suspected cells and normal control cells to progressively more hypotonic solutions and compares their ability to resist lysis.

HEREDITARY ELLIPTOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS

The findings on the peripheral blood smears in hereditary elliptocytosis and hereditary pyropoikilocytosis are distinct (Fig. 46-7). Hereditary elliptocytosis is an autosomal dominant condition characterized by elliptical RBCs. In hereditary pyropoikilocytosis, the RBC morphology is bizarre, marked by fragments, elliptocytes, and spiculated cells. The disorders are caused by defects in various proteins; the defects weaken the structural interactions necessary for cellular stability and reversible deformability.[11] The RBCs tend to retain deformed shapes and are cleared by the reticuloendothelial system. Hemolysis in hereditary elliptocytosis generally is milder than in hereditary spherocytosis, although patients with hereditary elliptocytosis can exhibit hemolysis and hyperbilirubinemia in the neonatal period. Persons with hereditary pyropoikilocytosis have inherited genes encoding abnormal structural proteins (e.g., hereditary elliptocytosis alleles) from each parent. Hereditary pyropoikilocytosis is associated with more severe hemolysis and hyperbilirubinemia, often requiring exchange transfusion or phototherapy in the neonatal period.[23] Examination of blood smears from each parent is helpful in making this diagnosis.

Membrane Lipid Defects

Membrane lipid abnormalities can be inherited but most often are acquired. Their presence, detected by morphologic abnormalities on the peripheral blood smear, usually is most important as the signal of an underlying disease. Target cells form when the surface-to-volume ratio of the red blood cell

increases, either because of poorly hemoglobinated cells (iron deficiency, thalassemias, Hb C) or because lipids are added to the RBC membrane (liver disease with intrahepatic cholestasis, lecithin-cholesterol acyltransferase deficiency). Acanthocytes form when the membrane lipid composition is altered between the inner and outer leaflets of the bilayer, as in liver disease and abetalipoproteinemia.[34]

Inherited Enzymatic Defects

The mature RBC, lacking a nucleus, polyribosomes, and mitochondria with which to perform protein synthesis, must circulate through extremes of pH, P_{O_2}, and osmotic gradients while maintaining deformability and integrity. It also must metabolize glucose through the Embden-Meyerhof pathway and hexose monophosphate shunt to provide energy for maintaining ionic pumps, to achieve reduction of methemoglobin to hemoglobin, and to synthesize small molecules such as adenine, guanine, pyrimidine nucleotides, glutathione, and lipids. Defects in the enzymatic machinery of the erythrocyte have been studied since the 1940s. The most commonly affected enzyme, G6PD, has been extensively evaluated at the clinical, biochemical, and molecular level.[17] Many other enzymatic defects have been reported, but the rarity of the disorders has hindered investigation. Enzymatic defects of the RBC known to be associated with hemolytic anemia are listed in Box 46-3. A few of the enzyme deficiencies cause abnormalities in other tissues. The end result of these defects is hemolytic anemia of varying severity, sometimes called *hereditary nonspherocytic anemia*. The RBCs are generally morphologically normal and usually produce normal results on osmotic fragility testing, but they have a shorter life span. The milder cases cause little difficulty in the neonatal period. Occasionally, the hemolysis is severe, requiring chronic transfusion therapy and encouraging investigators to evaluate the possibilities of gene transfer therapy.

G6PD deficiency is the only common defect of RBC enzymes, and its prevalence among some ethnic groups initiated studies that suggested a selective advantage for

deficiency in areas where *Plasmodium falciparum* malaria occurred. As an enzyme in the pentose phosphate pathway, G6PD supplies NADPH and reduced glutathione to the RBC. Deficiency limits the cell's ability to recover from oxidative stress. The gene is X-linked recessive in inheritance; males are affected most commonly, but females may also be affected in cases in which X-inactivation is unbalanced. Eleven variants have been described among various ethnic groups. In the United States, African-American males are the most commonly affected, with an estimated prevalence of 11% to 14%.[17] The A-minus variant, common in the African population, shows a mild reduction in both catalytic activity and stability. The variant common among Mediterranean, some Asian, and Ashkenazi Jewish populations involves a severe reduction of enzyme activity, resulting in chronic moderate to severe hemolytic anemia that could prove fatal in the face of severe oxidant challenge. In affected patients, the oldest RBCs are most deficient, resulting in a normal or minimally shortened erythrocyte life span, but exposure to oxidant drugs and toxins or a febrile episode can precipitate severe hemolysis. Hemolysis occurs within 24 to 48 hours of exposure and is accompanied by abdominal pain, vomiting, diarrhea, low-grade fever, jaundice, splenomegaly, hemoglobinuria, and anemia.

Neonates may present with hemolytic anemia and hyperbilirubinemia within 24 hours of life and are susceptible to developing methemoglobinemia (see later). Management involves avoidance of precipitating agents, hydration, phototherapy, and, if needed, transfusion (partial volume exchange or simple). Common drugs to be avoided or used with caution in this disorder include antimalarials, sulfonamides and sulfones, nitrofurans, anthelminthics, ciprofloxacin, methylene blue, acetaminophen, aspirin, and vitamin K analogues. Enzyme levels are highest in younger cells, and evaluation immediately after a hemolytic episode could be inconclusive because the older, more biochemically abnormal cells have been destroyed. Repeat quantitative testing at a later time, as well as evaluation of maternal enzyme levels, can be useful. Genetic testing of the common variants is available. Some states and countries include G6PD deficiency screening as part of their newborn screening program.

Vitamin E Deficiency

Vitamin E (α-tocopherol) is a fat-soluble antioxidant that reduces the peroxidation of polyunsaturated fatty acids by reactive oxygen species during oxidative enzyme activity. Preterm infants and infants with low birthweight have low serum and tissue levels of this vitamin. Patients who have cystic fibrosis or other causes of chronic fat malabsorption are the most likely to develop symptomatic vitamin E deficiency. A deficiency state in preterm infants and those with very low birthweight has been described, characterized by hemolytic anemia, reticulocytosis, thrombocytosis, chronic lung disease, intracranial hemorrhage, and retinopathy of prematurity. In a 2003 Cochrane review[11] of 26 randomized controlled clinical trials, vitamin E supplementation in preterm infants was found to lower the risk for intracranial hemorrhage but increase the risk for sepsis. Similarly, it was associated with reduction of severe retinopathy of prematurity and blindness in infants with very low birthweight but increased the risk for sepsis. There was a small increase in hemoglobin level. Evidence does not support supplementation with intravenous or high-dose vitamin E.

The Thalassemias

The thalassemias are a group of hereditary anemias that arise from defects in the synthesis of globin chains. In their milder forms, thalassemias are among the most common heritable disorders. The α-thalassemias are most common in the Chinese subcontinent, Malaysia, Indochina, and Africa. β-Thalassemia is common in Mediterranean and African populations but also has a higher incidence in China, Pakistan, India, and the Middle East. The four α-thalassemia syndromes (silent carrier, α-thalassemia trait, Hb H disease, and hydrops fetalis) are caused by diminished production of α-globin protein due to defects in one, two, three, or four of the α-globin genes, respectively. There is considerable heterogeneity within these four categories because the clinical outcome is affected by whether the genetic defects result in diminished or absent expression of each of the affected genes. Although only two genes for β-globin production are inherited, there also are four clinical classifications for β-thalassemia: silent carrier, β-thalassemia trait, thalassemia intermedia, and thalassemia major. The clinical outcome in this disease is a result of complex interactions involving the type of genetic defect, the degree of β-globin production, and the ratio of α-globin chains produced relative to the number of β-globin chains. Coinheritance of α-globin and β-globin defects may result in a less severe thalassemia because the ratio of α-globin to β-globin chains is rebalanced.

Prenatal diagnosis strategies are available for both α- and β-thalassemia. If evaluation of the parents' RBCs produces evidence of thalassemia, molecular detection strategies can be undertaken. After 18 to 20 weeks' gestation, fetal reticulocytes may be tested for globin chain biosynthetic ratios. Fetal tissue from chorionic villus sampling or amniocentesis can be analyzed by a number of DNA-based methodologies (see Chapter 8).

α-THALASSEMIA

Because the production of α-globin chains predominates from mid-gestation onward, defects in α-globin synthesis can be detected at birth. Before the debut of molecular analysis, the various α-thalassemia syndromes were assigned according to clinical criteria. Hydrops fetalis, the most severe and rarest form of α-thalassemia, occurs when an infant inherits deletions of both α-globin genes from each of the parents (see Chapter 21). Such an infant produces small quantities of Hb Portland to maintain in utero viability. The excess γ and β chains form tetramers with themselves, resulting in functionally useless Hb Barts (γ_4) present in the newborn and Hb H (β_4) present in the older infant. The tetramers accumulate in the bone marrow and reticuloendothelial system, resulting in ineffective erythropoiesis. These mutant hemoglobins can precipitate to form inclusion bodies that adhere to cell membranes, promote oxidative damage to the membrane, diminish cell deformability, and shorten RBC survival. The blood smear shows hypochromic microcytes, target cells, and nucleated RBCs. Bizarre RBC shapes and fragments are also common. The fetus with four α-globin gene defects experiences congestive heart failure in utero secondary to severe anemia and, in the absence of fetal transfusion, becomes grossly hydropic (hydrops fetalis). There is evidence of extensive extramedullary hematopoiesis and placental hypertrophy. Most are stillborn at 30 to 40 weeks' gestation or die shortly after delivery. Infants with hepatosplenomegaly, jaundice, and a moderate hypochromic, microcytic hemolytic anemia should be evaluated for deletion of three α-globin genes, Hb H disease. At birth, large amounts of Hb Barts may be seen as well as Hb H. Incubation of the RBCs with brilliant cresyl blue reveals many small inclusions. Treatment is supportive and includes supplementation with folic acid, avoidance of oxidant drugs, transfusion of RBCs, and recognition and treatment of the patients as having compromised splenic function. Hypersplenism, characterized by leukopenia, thrombocytopenia, and worsening anemia, might necessitate splenectomy, although this usually is deferred beyond the first few years of life. Iron overload from chronic transfusions is a significant cause of morbidity and mortality.[37]

α-Thalassemia trait is characterized by a mild anemia with microcytosis, hypochromia, and erythrocytosis. Hb Barts is mildly elevated, 4% to 6% at birth. After the neonatal period, there is no simple laboratory evaluation that is diagnostic for α-thalassemia trait, although β- to α-biosynthetic ratio of reticulocytes or restriction endonuclease mapping can be performed. The diagnosis usually is made in an iron-replete patient with a normal hemoglobin electrophoresis and appropriate family history for α-thalassemia. As the name implies, silent carriers of α-thalassemia could have slightly microcytic RBCs but usually are asymptomatic. Several states now use molecular testing for *HBA1* and *HBA2*, the genes coding for α_1-globin and α_2-globin, respectively.[37]

β-THALASSEMIA

β-Thalassemia is not usually diagnosed at birth unless blood loss or RBC destruction has created an unusually high demand for replacement of RBCs. The disease generally manifests after 6 months of age, when a microcytic anemia persists beyond the time course for physiologic anemia. The more severe manifestations of the disease traditionally were called *Cooley anemia*, but these have been separated into *thalassemia major* and *thalassemia intermedia*. Affected patients exhibit splenomegaly, poor growth, microcytic hemolytic anemia with ineffective erythropoiesis, target cells on the peripheral blood smear, and extramedullary expansion of erythropoiesis. An abnormal hemoglobin analysis reveals elevations of Hb F and Hb A_2 and a decrease in Hb A.[37]

Patients are categorized as having thalassemia intermedia if they are able to maintain a hemoglobin level greater than 7 g/dL without routine transfusion. Thalassemia major patients require regular transfusions and iron chelation therapy to maintain a hemoglobin value adequate for growth and development. Iron overload is a significant cause of morbidity and mortality starting in the second decade of life. Evidence of hypersplenism might necessitate splenectomy in either type of patient. Bony deformities from expansion of extramedullary hematopoiesis occur in incompletely transfused patients.

β-Thalassemia trait is characterized by abnormalities on the blood smear: microcytosis, hypochromia, erythrocytosis, and the appearance of elliptocytes and target cells. Occasionally, a patient has hepatosplenomegaly. Hemoglobin analysis generally is helpful because of a mild elevation of Hb A_2 and Hb F, although this is not true if the genetic mutation also interferes with production of δ-globin or γ-globin or if Hb A_2 and Hb F production are depressed because of coexistent iron deficiency anemia. The silent carrier state of β-thalassemia is associated with normal findings on the peripheral blood smear and hemoglobin electrophoresis and usually is identified by family studies of patients with a more severe β-thalassemia syndrome.

Hemoglobin Variants

In the fetus, switching from one type of globin chain expression to another occurs several times (see earlier), and over the first few months of the postnatal period, the final switch to the adult-type hemoglobin ($\alpha_2\beta_2$) occurs. Some hereditary defects in fetal globin gene products can produce a hemolytic anemia that resolves as β-globin gene expression predominates. Similarly, a neonate who is asymptomatic at birth can develop a hemolytic anemia over the subsequent months as production of β-globin–containing hemoglobin assumes major importance. Because α chains are produced from the fetal period onward, defects in α-globin are present at birth. If the combination of the mutant α-globin and the γ-globin is more unstable than that of α- and β-globin or α- and δ-globin, the infant experiences a transient hemolytic anemia that resolves as Hb A predominates.

More than 500 structurally different hemoglobin variants have been reported.[47] Several of the important variants are summarized in Box 46-4. Most involve a single amino acid substitution in one of the globin polypeptide chains due to a single nucleotide change in DNA. Other variants are the result of gene deletions or fusions due to uneven crossover. Some of the more commonly important hemoglobin mutations are discussed later.

HEMOGLOBIN S AND SICKLE CELL ANEMIA

Sickle cell (Hb SS) disease is a common medical problem in the United States, where 1 in 400 newborns is affected. By definition, *sickle cell anemia* refers to the doubly heterozygous inheritance of abnormal genes that code for the substitution of valine in place of glutamic acid at position 6 in the β chain of hemoglobin. There are a number of other sickle hemoglobinopathies in which one gene coding for Hb S is inherited along with a second abnormal β-globin gene coding for other hemoglobins, such as Hb C or β-thalassemia. The clinical courses of affected patients may be indistinguishable from, or milder than, those of Hb SS disease. As with the thalassemias, prenatal diagnostic techniques are available. Newborn screening programs have been instituted (Fig. 46-8) in many parts of the world, including much of the United States. Samples of cord or capillary blood are subjected to testing, usually hemoglobin electrophoresis or isoelectric focusing. Infants with electrophoretic patterns demonstrating Hb S and Hb F but not Hb A are presumed to have sickle cell anemia and are referred for confirmatory testing and disease counseling. This screening method also identifies patients with Hb SC disease.

Hb WITH ABNORMAL OXYGEN AFFINITY
High affinity—erythrocytosis
Low affinity—cyanosis
Hb M (a cause of congenital methemoglobinemia)

Hb, hemoglobin.

Heterozygotes for Hb S (sickle cell trait) were thought to be clinically unaffected but there are reports of hematuria, decreased urinary concentrating ability, and occasional reports of sudden death related to high altitude and extreme exercise. Associations have been made between sickle cell trait and venous thrombosis, renal medullary carcinoma, and a more severe course of diabetes mellitus.

The clinical hallmark of Hb SS disease is hemolytic anemia with reticulocytosis and the appearance of irreversibly sickled cells on the peripheral blood smear. The onset of signs and symptoms correlates with the decrease in Hb F and increasing expression of the mutant β-globin gene products during the first year of life. Neonates generally are asymptomatic, although older infants are at risk for several disease-related complications. Problems reported in neonates include fever, hepatosplenomegaly, and hyperbilirubinemia. Because of splenic dysfunction, bacterial infections are a major cause of mortality and morbidity in infants and young children. A suddenly pale, listless infant may be experiencing life-threatening anemia caused by hepatic or splenic sequestration. Aplastic crisis, triggered by infection or drugs, also may occur. Vaso-occlusive pain crises most commonly occur in infants' hands and feet. Hand-foot syndrome (dactylitis) manifests with pain, warmth, and swelling of the hands and feet.

Identification of affected newborns through newborn screening programs and enhancements in parent education and supportive care such as penicillin prophylaxis until the sixth year of life, immunization against *Streptococcus pneumoniae* and *Haemophilus influenzae*, and early identification of hepatic or splenic sequestration have decreased the death rate for infants and children. The natural history of sickle cell anemia includes stroke, pulmonary hypertension, overwhelming sepsis from splenic dysfunction, avascular necrosis of joints, retinopathy, acute and chronic lung disease, and transfusion-related iron overload.

Treatment of the sickle hemoglobinopathies has been largely supportive. Penicillin prophylaxis is recommended for all infants with sickle cell anemia. Blood transfusions may be needed to restore tissue oxygenation or to reverse a vaso-occlusive episode in a critical organ. Oral or intravenous chelation therapy decreases iron overload in chronically transfused patients. Extended RBC phenotyping and crossmatching decrease the incidence of transfusion-associated alloimmunization. Hydration, narcotics, and nonsteroidal antiinflammatory drugs are useful during painful crises. Hydroxyurea decreases the number and severity of vaso-occlusive events in many people with sickle cell anemia: its use in young children has been favorably reported. The Baby HUG study, looking at the effects of hydroxyurea therapy in infants as young as 9 months of age, is currently ongoing. Bone marrow transplantation, the only established cure for sickle cell anemia, has been limited by the availability of suitable donors and the uncertainty in predicting which children will express a more severe phenotype. Ongoing studies of less toxic preparative regimens for bone marrow transplantation and more inclusive donor options, as well as risk stratification of sickle cell patients, may allow larger number of patients to undergo bone marrow transplantation in the future.

HEMOGLOBIN E

Hemoglobin E is one of the most common hemoglobinopathies in the world. This mutant hemoglobin is particularly abundant among people of Southeast Asian ancestry, especially individuals from Laos, Cambodia, and Thailand. Hb E is caused by a single nucleotide substitution in the coding region of the β-globin gene. The resultant β-globin chain contains a Glu26Lys substitution, but it associates normally with α-globin to form a functional hemoglobin tetramer with essentially normal stability and oxygen-dissociation characteristics. Persons with Hb E are anemic because the mutation creates a cryptic splice site in the β-globin message. During RNA processing, a portion of the β-globin message is spliced into an abnormal, unstable transcript. Consequently, the total level of β-globin messenger RNA is reduced, resulting in a thalassemic phenotype. Those who are heterozygous or homozygous for Hb E have chronic, mild to moderate, microcytic anemia but are otherwise well. However, patients who inherit an Hb E allele from one parent and a β-thalassemia allele from the other have a moderate to severe anemia that can be transfusion dependent. Hb levels in these patients range from 2 to 7 g/dL, and children with this condition can develop hepatosplenomegaly and growth failure. Hb E-β thalassemia disease now is the most common form of transfusion-dependent thalassemia in the United States and other parts of the world. Hb E coinherited with sickle cell trait also results in a more severe sickle phenotype.

UNSTABLE HEMOGLOBINS

Most of these mutations affect β-globin and involve amino acid substitutions in hydrophobic residues around the heme pocket. These amino acid replacements alter the hydrophobic interior of the molecule, predisposing these molecules to instability and precipitation in the form of Heinz bodies. Because the amino acid substitutions often involve replacing one neutral amino acid with another, the hemoglobin electrophoretic mobility might not change. Patients usually develop anemia and jaundice in late infancy or early childhood as β-globin synthesis increases. Mutations in fetal or embryonic globins can cause symptoms at birth but not later in life. The diagnosis is confirmed by staining for Heinz bodies, which are usually present, and testing for hemoglobin stability.[47]

Anemia Caused by Inefficient Production of Red Blood Cells

IRON-DEFICIENCY ANEMIA

Although the prevalence of iron deficiency anemia is decreasing in the United States, it remains the leading cause of anemia in infancy and childhood. Factors associated with the declining rates of iron deficiency anemia include the increasing number of infants receiving breast milk, the extensive use of iron-supplemented infant formulas and baby cereals during the first year of life, and delaying introduction of cow's milk into the infant diet until after 1 year of age.

Iron is an essential nutrient. Most iron is bound to the heme proteins, hemoglobin, and myoglobin. The storage proteins, ferritin and hemosiderin, contain most of the rest, though a small percentage is bound in enzyme systems such as cytochromes and catalase. In healthy adults, most of the body's iron is recycled from the breakdown of RBCs; little iron needs to be absorbed from the intestines, and little is lost through fecal or urinary excretion. Because neonates must rapidly expand muscle mass and blood volume, they require a much higher percentage of dietary iron intake. The amount of iron stored in the neonate's body is proportionate to birthweight. For a full-term infant, this should be sufficient for the first 4 to 6 months of life. Preterm infants and those born small for gestational age weigh less at birth, have a much faster rate of postnatal growth, and are at risk for iron deficiency within the first 3 months of life (Table 46-10). Infants born anemic and those who have accelerated iron losses from repeated laboratory testing, trauma, surgery, or anatomic abnormalities may also become deficient. Babies born to mothers with iron deficiency anemia are at increased risk for developing iron deficiency anemia during the first year of life.

Although both breast milk and cow's milk contain iron, the bioavailability of the iron in breast milk is much superior. Full-term infants who are breast-fed should not require iron supplementation until 4 to 6 months of age. Two daily servings of an iron-fortified cereal will meet this requirement. Infants who are premature, ill, or have low birthweight and who are breast-fed will require supplementation as early as 2 months of age (Table 46-11). Formula-fed infants should be given an iron-supplemented formula. Infant cereal fortified with iron should be one of the earliest solid foods introduced. After 6 months of age, one daily serving of a vitamin C–rich food should be introduced. Because the protein in cow's milk can cause occult gastrointestinal bleeding in the neonate and because of the poor bioavailability of iron in cow's milk, it is recommended that babies avoid cow's milk until after 1 year of age.

TABLE 46–10 Risk Factors for Iron Deficiency Anemia in the First 6 Months of Life

- Prematurity
- Small for gestational age
- Anemia at birth
- Fetal-maternal hemorrhage
- Twin-twin transfusion syndrome
- Perinatal hemorrhage
- Erythropoietin use
- Maternal iron deficiency anemia
- Iatrogenic or other ongoing blood loss
- Insufficient dietary intake or malabsorption
- Early introduction of whole cow's milk

TABLE 46–11 Guidelines for Iron Supplementation for Breast-Fed Infants in the First Year of Life

Status at Birth	Minimum Daily Requirement (maximum 15 mg)	Begin By
Full-term	1 mg/kg	4 mo
Premature	2 mg/kg	2 mo
Very low birthweight (<1500 g)	3-4 mg/kg	2 mo

Adapted from American Academy of Pediatrics. Recommendations for preventive pediatric health care (periodicity schedule). http://practice.aap.org/content.aspx?aid=1599.

Iron deficiency in infancy has been associated with impairment of psychomotor development and may negatively affect social and emotional behavior. Whether these deficits are fully resolved by subsequent iron supplementation is unclear. Although severe iron deficiency is fairly simple to diagnose, milder deficiency may not yet have caused anemia or may be difficult to distinguish from other causes of microcytic anemia, especially in patients with chronic or acute illness. The American Academy of Pediatrics recommends that testing for anemia should include Hb or Hct values between ages 9 and 12 months. Given emerging information about the early effects of iron deficiency and identification of at-risk populations of infants, the American Academy of Pediatrics also recommends a risk assessment as early as 4 months of age for healthy infants. A careful dietary history should be taken, and consideration should be given to special circumstances such as ongoing blood loss, malabsorption, and birth history.

In early iron deficiency, the bone marrow stores are depleted, and the RBC distribution width increases. Subsequently, the iron transport levels fall, resulting in lower serum levels of iron, ferritin, and transferrin. Finally, erythrocyte production is affected. A hypochromic, microcytic anemia becomes apparent. Screening test results such as serum iron, total iron-binding capacity, ferritin, and transferrin saturation may be inconclusive because of acute or chronic illness. A therapeutic trial of iron for presumptive iron deficiency anemia is a cost-effective strategy. Ferrous sulfate, in a dose of 2 to 6 mg/kg per day of elemental iron, may be given for 1 month. If the hemoglobin rises by at least 1 g/dL (in the absence of ongoing blood loss), the diagnosis of iron deficiency is made, and the iron supplementation should be continued for 2 or 3 more months or until 1 or 2 months after the Hb and Hct values are in the normal range. Screening for lead exposure should be done as part of routine well-baby care and particularly considered if a hypochromic, microcytic anemia is detected.

ANEMIA OF PREMATURITY

Anemia of prematurity is characterized by a low reticulocyte count and an inadequate response to erythropoietin (EPO). Infants with extremely low birthweight often undergo transfusion because they are critically ill, need artificial ventilation, and have the highest blood sampling loss in relation to their weight. More centers are using restrictive transfusion guidelines and have been able to decrease the number of transfusions and donor exposures. Although appreciable levels of EPO are present in the serum of most premature infants, the neonate produces an insufficient amount of this growth factor and is amenable to pharmacologic supplementation with recombinant EPO.

Multiple placebo-controlled trials have established that EPO therapy effectively increases reticulocyte counts and hematocrit.[62] Unfortunately, in most studies, although the total volume of blood transfused was reduced, donor exposures were not reduced. Thus, EPO alone does not appear to be an effective strategy to reduce transfusion needs. It remains to be seen if blood conservation, combined with EPO replacement, will be effective in reducing transfusions.

TRANSIENT ERYTHROBLASTOPENIA OF CHILDHOOD

Transient erythroblastopenia of childhood is an acquired, transient, normocytic, hypoplastic anemia affecting children. The etiology of transient erythroblastopenia is unknown but is postulated to be the result of viral injury to erythroid precursors. Familial cases have been reported. This syndrome is exceedingly rare in neonates; most cases of the condition cluster at 2 to 3 years of age. The degree of anemia can range from moderate to severe. Occasionally, hemoglobin levels as low as 3 g/dL are seen. Transient erythroblastopenia is a diagnosis of retrospect. Treatment consists of supportive measures, including RBC transfusion if needed, until bone marrow recovery. Most patients recover in 1 to 2 months. The condition may be confused with Diamond-Blackfan anemia and parvovirus-induced anemias.

PARVOVIRUS-INDUCED ANEMIA

Parvovirus B19, which proliferates in human erythroid precursors, causes several diseases. In normal children or adults, the virus produces fifth disease. Thirty to 60% of adults in the United States have antibody to the virus.[29] The rash and joint symptoms associated with this generally minor illness are due to vascular deposition of antibody complexes generated in response to the infection. In patients with underlying hemolytic anemias (e.g., sickle cell anemia or hereditary spherocytosis), parvovirus infection can cause a transient, severe aplastic crisis. The virus also can cause chronic anemia by means of a persistent infection in erythroblasts in immunocompromised hosts. Chronic parvovirus anemia responds to administration of intravenous γ-globulin that contains antiparvovirus antibody.

The virus binds to blood group P-antigen on the surface of erythroid precursors, is internalized, and then replicates, disrupting normal erythroid differentiation. P-antigen is also expressed on cells not known to be permissive for parvovirus replication. Endothelial cell P-antigen is postulated to participate in placental transmission of the virus. This antigen is also found on fetal cardiomyocytes, a finding consistent with the fact that the fetus infected with parvovirus can develop myocarditis. Infection rate during pregnancy is estimated to be in the 3% range. Parvovirus infection during pregnancy can result in anemia, hydrops fetalis (see Chapter 22), fetal loss, or congenital infection. The rate of transplacental transmission of the virus has been estimated at 33%. Initial reports of more than 30% rates of stillbirth and fetal loss have been reduced, and it is recognized that most of the mortality occurs during the first 20 weeks of gestation. Fetal loss associated with the infection is 11% before 20 weeks and less than 1% after this point in gestation. Hydrops is reported in 3.9% of infections diagnosed before 32 weeks of gestation, compared with 0.8% after this time.[29] Severe thrombocytopenia occurs in more than one third of cases and can complicate intrauterine transfusion. Parvovirus-induced hydrops can be detected by ultrasound, and treatment of suspected hydropic infants includes intrauterine RBC transfusion. Parvovirus infection of the fetus may persist after birth as a cause of congenital RBC aplasia.

DIAMOND-BLACKFAN ANEMIA

Diamond-Blackfan anemia is a rare syndrome of congenital macrocytic anemia with reticulocytopenia.[7] The median hemoglobin at birth for these patients is 7 g/dL, and the reticulocyte count usually is 0% to 1%. Bone marrow examination reveals decreased numbers of erythroid precursors and abnormal erythroid maturation. Serum EPO levels are elevated as a compensatory response to inefficient RBC production by the marrow. RBC adenosine deaminase levels also are elevated in this syndrome. Patients with Diamond-Blackfan anemia often have one or more physical anomalies, such as low birthweight, short stature, abnormal facies, skeletal abnormalities (including abnormal thumbs), and visceral anomalies. The median age of diagnosis is 2 months. Although the phenotypes of Diamond-Blackfan anemia and Fanconi anemia overlap, several features distinguish these syndromes. Patients with Diamond-Blackfan anemia are anemic from birth, whereas those with Fanconi anemia generally develop reticulocytopenia later in life. Finally, laboratory evaluation reveals increased chromosome fragility in Fanconi cells but not in Diamond-Blackfan anemia cells.

Erythroid precursors from patients with Diamond-Blackfan anemia display abnormal maturation in vitro, and the syndrome can be corrected by allogeneic bone marrow transplantation, indicating that it is caused by a defect in stem cell differentiation. Family studies have documented autosomal dominant and autosomal recessive patterns of inheritance. Several genes have been identified whose mutations together account for about 45% of patients with Diamond-Blackfan anemia. All mutations identified affect proteins of the small (RPS) or large (RPL) ribosomal subunit, suggesting that this is a disorder of ribosome biogenesis.[7] Heterozygous mutations in *RPS19* are evident in 25% of cases.

About two thirds of patients with Diamond-Blackfan anemia respond to glucocorticoid therapy with an increase in Hb concentration and the reticulocyte count. Prednisone therapy usually is initiated at a dose of 2 mg/kg per day, and an increase in the reticulocyte count generally is noted in 1 to 2 weeks. For glucocorticoid responders, the prednisone dose is slowly tapered until the patient is on an alternate-day dose that maintains a reasonable Hb level. Many patients remain on small alternate-day doses of steroids for years. Steroid nonresponders are managed with chronic RBC transfusion therapy, with the long-term complication of iron overload. Chelation therapy is indicated when transfusion-dependent patients develop significantly increased iron stores, as documented by an elevated serum ferritin value greater than 1000 ng/mL or increased urinary excretion of iron after a desferrioxamine challenge. Bone marrow transplantation from an HLA-matched unaffected sibling is a consideration for transfusion-dependent patients.

Despite advances in medical therapy, patients with Diamond-Blackfan anemia have a shortened expected life span. As is true for other congenital bone marrow failure syndromes, Diamond-Blackfan anemia is associated with an increased risk for aplastic anemia, myelodysplastic syndrome, and acute leukemia later in life.

FANCONI ANEMIA

Although Fanconi anemia is not a cause of pure anemia in the neonate, this congenital bone marrow failure syndrome is discussed here in the context of other congenital hematologic diseases. Originally characterized as familial aplastic anemia with birth defects, the condition has been extended to include patients with characteristic chromosome fragility findings, with or without aplastic anemia, and with or without birth anomalies.[7] Hematologic abnormalities other than macrocytosis usually are not evident in infants with Fanconi anemia. The condition often is not recognized until the onset of aplastic anemia, at a mean age of 8 years.

The physical anomalies associated with Fanconi anemia are listed in Table 46-12. Only a minority of Fanconi patients have thumb anomalies, the birth defect traditionally associated with this condition.

Cells from patients with Fanconi anemia exhibit increased chromosome breakage in response to certain alkylating agents, and this now is the basis of diagnostic testing for this condition. Patient lymphocytes are cultured and exposed to the alkylating agent diepoxybutane, and then metaphase smears of the chromosomes are examined for breaks. Complementation studies using somatic cell hybrids have shown that mutations in at least seven genes can produce the Fanconi anemia phenotype.

The proteins encoded by the *FANC-A, -C, -E, -F, -G, -L*, and *-M* genes assemble into a multisubunit nuclear complex. DNA damage caused by alkylating agents activates this protein complex, leading to monoubiquitination of *FANC-D2*, which interacts with the tumor suppressor *BRCA1* to effect DNA repair. The product of the "*FANC-D1* gene" is *BRCA2*, another tumor suppressor that physically interacts with *BRCA1*. Researchers postulate that disruption of the Fanconi anemia complex and impaired monoubiquitination of *FANC-D2* result in the cellular and clinical phenotypes common to most of the complementation groups.[7]

TABLE 46–12 Physical Anomalies Associated with Fanconi Anemia

Anomaly	Percentage
Skin hyperpigmentation or café-au-lait spots	76
Microsomy	65
Low birthweight	47
Thumb anomalies	40
Hypogenitalia	33
Renal anomalies	32
Skeletal anomalies (except thumbs)	28
Strabismus	23
Microphthalmia	19
Mental retardation	18
Ear anomalies or deafness	12
Congenital heart disease	7

Adapted from Alter BP, et al: Long-term outcome in Fanconi's anemia: description of 26 cases and a review of the literature. In German J, editor: *Chromosome mutation and neoplasia,* New York, 1983, Alan R Liss.

Hematopoietic progenitor cells from patients with Fanconi anemia display a distinct hypersensitivity to interferon-γ, which causes apoptosis of these progenitor cells. Interferon-γ hypersensitivity might account for the development of progressive bone marrow failure in these patients.

CONGENITAL DYSERYTHROPOIETIC ANEMIAS

Patients with these rare disorders have congenital anemia with ineffective, morphologically abnormal erythroid production. The degree of anemia can range from moderate to severe and can be macrocytic, normocytic, or microcytic. Type II is the most common of the three described types. The bone marrow shows multinucleated RBC precursors and asynchrony in the maturation of erythroid nuclei and cytoplasm. Defects in glycosylation of erythroid precursor surface glycoproteins and glycolipids have been associated with some cases. The disease often remains undiagnosed in the neonatal period, although many patients are noted to have anemia and jaundice early on. Dysmorphic features can be associated with the anemia.[74] Management includes transfusion and chelation of iron excess. Bone marrow transplantation has been attempted in severe cases.

SIDEROBLASTIC ANEMIAS

The sideroblastic anemias are congenital hypochromic, microcytic, or normocytic anemias that are unresponsive to iron therapy. Both X-linked and autosomal varieties exist. Acquired sideroblastic anemia occurs later in life. These anemias are caused by abnormalities in the mitochondrial enzymes of the heme biosynthetic pathway. Adequate iron stores are available, but iron is not incorporated into heme. The iron accumulates in the mitochondria of the nucleated erythrocyte and forms a ring around the nucleus. Prussian blue staining of the marrow reveals erythroid hyperplasia and large numbers of these ringed sideroblasts. Some respond to pharmacologic doses of pyridoxine because some of the heme biosynthetic enzymes (e.g., aminolevulinic acid synthetase) use this vitamin as a cofactor. Bone marrow transplantation has been suggested as a treatment for severe disorders.

Pearson syndrome is a refractory sideroblastic anemia characterized by vacuolization of bone marrow precursors due to deletion of mitochondrial DNA. The disease is frequently associated with exocrine pancreatic insufficiency, hepatic failure, and renal tubular dysfunction. The disorder becomes evident during early infancy, and most patients die before the age of 3 years.

Other Erythrocyte Disorders

METHEMOGLOBINEMIA

Methemoglobinemia results when methemoglobin production is increased or when the ability to reduce methemoglobin is decreased. For hemoglobin to reversibly bind oxygen, the heme iron must be in the ferrous (Fe^{2+}) state. As the RBC circulates and is exposed to various oxidants, the oxyhemoglobin is slowly oxidized to methemoglobin in the ferric

(Fe^{3+}) state. Partial oxidation of hemoglobin markedly increases the oxygen affinity of the other hemes in the tetramer and decreases oxygen delivery to tissues. Reduction of methemoglobin in the RBC depends largely on two electron carriers, cytochrome-b_5 and NADH, as well as the enzyme cytochrome-b_5 reductase. An alternate pathway using G6PD to generate NADPH in the hexose monophosphate shunt can be driven by the addition of electron carriers such as methylene blue. It is estimated that methemoglobin accumulates in adults at a rate of 2% to 3% a day, but RBCs with an intact cytochrome-b_5 reductase system contain less than 0.6% methemoglobin.[53] Neonates and premature infants have a transient enzymatic deficiency and lower cytochrome-b_5 levels for the first few months of life. Ingestion of nitrates, usually from contaminated well water, and their subsequent conversion to oxidizing nitrites by gut bacteria, are the leading cause of acquired methemoglobinemia in infants. Although the cause is unclear, there is an association between diarrheal illness in infants and methemoglobinemia even when toxin exposure has not been detected. Xylocaine and its derivatives and dapsone are the most common drugs precipitating methemoglobinemia.

Cyanosis occurs when relatively high levels of deoxyhemoglobin are present (generally, >5 g/dL) or when a nonphysiologic hemoglobin (e.g., methemoglobin) is present (>1.5 g/dL). The differential diagnosis of cyanosis is addressed in Chapters 44 and 45. Congenital methemoglobinemia is due either to a defect in the cytochrome-b_5 reductase system or to inheritance of one of the M hemoglobins (Hb M), which have an alteration in either the α or β chain, resulting in preferential binding of ferric iron. Acquired methemoglobinemia is caused by metabolic acidosis and exposure to certain drugs and chemicals with oxidant potential, such as nitrites. Neonates are at higher risk for developing toxic methemoglobinemia from environmental toxins and pharmacologic agents. The onset of symptoms in patients with one of the M hemoglobins corresponds with expression of the affected globin chains. Patients with cytochrome-b_5 reductase deficiency type I are asymptomatic other than cyanosis; the more rare type II disease presents with cyanosis, failure to thrive, and a severe neurologic phenotype. Many with type II disease die in infancy.

Patients have cyanosis that is unresponsive to oxygen therapy. Their blood is a characteristic chocolate brown. A fresh sample of blood is analyzed by co-oximetry to detect absorbance in the 630-nm range. False-positive tests results may be due to the presence of other pigments that absorb near the same wavelength, such as sulfhemoglobin and methylene blue.[53] Confirmatory testing of positive results is performed by the Evelyn-Mally method, in which the addition of cyanide abolishes absorbance methemoglobin at 630 nm. Hb analysis identifies abnormal hemoglobin in patients with M hemoglobins. Both quantitative and qualitative tests are available for evaluating defects in the cytochrome-b_5 reductase system.

Inheritance of the Hb M variants is autosomal dominant, whereas defects in the cytochrome-b_5 reductase system are inherited in an autosomal-recessive fashion. Homozygotes and compound heterozygotes usually are affected, but heterozygotes can become symptomatic after exposure to oxidant drugs or toxins. Patients with congenital methemoglobinemia may be cyanotic but otherwise asymptomatic. Similarly, patients with chronic methemoglobinemia, with methemoglobin levels of up to 40% or 50%, may be physiologically well compensated and exhibit minimal symptoms. Acute methemoglobinemia with levels above 20% produces the signs and symptoms of hypoxia. Levels greater than 70% can result in coma and death, although there are reports of neonates who survived levels as high as 85%.[53]

Therapy is initiated for symptomatic patients with cytochrome-b_5 reductase deficiency and those with methemoglobin levels above 40%. The usual treatment is oral methylene blue, given in a dose of 1 to 2 mg/kg. If the patient does not show a good response within 1 hour, the treatment may be repeated, although consideration should be given that the patient could have G6PD deficiency. Patients with G6PD deficiency should not be treated with methylene blue because it is often not beneficial and it also causes oxidant stress and hemolysis. Alternative therapy with ascorbic acid, 200 to 500 mg/kg per day, may be used with caution because of concerns about calcium kidney stone formation. High-dose ascorbic acid also has oxidant potential and can trigger hemolysis in G6PD-deficient patients. No treatment exists for those with Hb M variants. All patients with congenital methemoglobinemia and known heterozygotes for cytochrome-b_5 reductase deficiency should avoid aniline derivatives and nitrates.

POLYCYTHEMIA

Polycythemia is defined as an increase in RBC mass more than 2 standard deviations above mean for age and gestation. For a term infant, polycythemia occurs when a peripheral venous blood sample has an Hb greater than 22 g/dL or a hematocrit greater than 65%. Capillary blood samples are generally higher than those drawn from peripheral blood, and central venous values are lower still. The real issue is viscosity, which has a linear relationship to the hematocrit up to about 60%. Blood viscosity increases more rapidly above 60% hemacrit, but less predictably.[69] Laboratory testing for hyperviscosity is not generally available, so decisions are made using the hematocrit or hemoglobin and clinical symptoms. Symptoms include listlessness, irritability, plethora, acrocyanosis, poor feeding, hypoglycemia, respiratory distress, and systemic thromboses. Persistent pulmonary hypertension of the newborn can be caused by increased pulmonary vascular resistance. The increased load of RBCs also contributes to hyperbilirubinemia. Symptoms often appear at or after 2 hours of life, when the hematocrit is highest due to fluid shifts. Some patients with excessive extracellular fluid losses may become symptomatic on day 2 or 3 of life.

Conditions that result in transfusion to the fetus, such as twin-twin or maternal-fetal transfusion or delayed clamping of the umbilical cord, can cause polycythemia. Exacerbations in the degree of intrauterine hypoxia, such as may be seen with placental insufficiency, maternal toxemia, and postmaturity, trigger increased production of EPO, which causes an increase in RBC mass. Maternal smoking has been associated with symptomatic polycythemia in infants. Several endocrine conditions are associated with increased RBC production and polycythemia, including maternal diabetes, hyperthyroidism or hypothyroidism, and congenital adrenal hyperplasia. Excessive EPO production and polycythemia also are seen in infants with Down syndrome and some other trisomies and

Beckwith-Wiedemann syndrome. Less commonly, an alteration in hemoglobin can greatly increase the affinity of the hemoglobin for oxygen, but most of the cases described have involved β-chain defects that would be expected to manifest later in infancy. Hereditary defects in the EPO receptor associated with polycythemia also have been reported.

Management remains controversial for most infants because exchange transfusion is associated with the usual transfusion risks as well as increased risk for necrotizing enterocolitis. Asymptomatic infants with a hematocrit of 60% to 70% should be monitored closely with adequate hydration and glucose levels. Symptomatic patients and those with a central hematocrit greater than 70% more often undergo partial volume exchange transfusion with normal saline to reduce the RBC mass (see Part 2 of this chapter), but some are still managed with supportive care.

PHAGOCYTES

Normal Physiology of Phagocytes

FUNCTION OF PHAGOCYTES

Leukocytes serve as major effector cells for host defense against invading organisms. Neutrophils circulate in the blood until they encounter specific chemotactic signals that promote adhesion to the vascular endothelium and migration through (diapedesis) and movement to the sites of microbial invasion (chemotaxis). Mononuclear phagocytes (monocytes, macrophages) function primarily as cells resident within certain tissues such as the spleen, lungs, and peritoneum, where they interact closely with lymphocytes to generate a local immune response. Both neutrophils and mononuclear phagocytes take up opsonized targets (internalization, phagocytosis), which are then destroyed within intracellular vacuoles by the release of hydrolytic enzymes and reactive oxygen intermediates (respiratory burst activity).

NUMBER OF PHAGOCYTES

Changes in the number of circulating leukocytes could represent either disordered leukocyte production or disordered leukocyte consumption, or both. *Neutropenia* is defined as a neutrophil blood count of less than 1500/µL. Although this definition is generally used for all ages and races, in the newborn the absolute neutrophil count (ANC) is elevated for the first few days of life. The ANC is the product of the total white blood cell (WBC) count and the percentage of mature neutrophils plus percentage of bands:

$$\text{ANC} = \text{WBC} \times (\%\ \text{neutrophils} + \%\ \text{bands}) \times 0.01$$

Neutrophilia is an elevation of the blood neutrophil count greater than 2 standard deviations above the mean.

Human myelopoiesis begins in the embryo (about 8 weeks). By 20 weeks of gestation, neutrophils demonstrate partial functional activity. However, even neutrophils from the normal newborn display limited functional activity. Neutrophil counts vary considerably during the neonatal period (Table 46-13), with a mean of 11,000/µL and a range of 6000 to 26,000/µL. Total WBC counts may be as high as 38,000/µL within 12 hours of age. However, after the first 12 hours of life, neutrophil counts fall, reaching a mean of about 5000/µL (1000 to 10,000) in the first week of life. The WBC differential during this period resembles that of adults, with a majority of neutrophils. However, during the next 5 years, lymphocytes predominate in the peripheral blood differential. There is substantially greater variability in the changes from birth onward for the first several weeks of life in a premature infant.

TABLE 46–13 Polymorphonuclear Leukocyte and Band Counts in the Newborn During the First 2 Days of Life*

Age (hr)	Absolute Neutrophil Count (per µL)	Absolute Band Count (per µL)	Band-to-Neutrophil Ratio
Birth	3500-6000	1300	0.14
12	8000-15000	1300	0.14
24	7000-13000	1300	0.14
36	5000-9000	700	0.11
48	3500-5200	700	0.11

*Normal values were obtained from the assessment of 3100 separate white blood cell counts obtained from 965 infants; 513 counts were from infants considered to be completely normal at the time the count was obtained and for the preceding and subsequent 48 hours. There was no difference in the normal ranges when infants were compared by either birthweight (whether more or less than 2500 g) or gestational age.

Modified from Manroe BL, et al: The differential leukocyte count in the assessment and outcome of early-onset neonatal group B streptococcal disease, *J Pediatr* 91:632, 1977.

KINETICS OF PHAGOCYTES

The circulating blood neutrophil pool reflects a dynamic equilibrium among several compartments: within the bone marrow are the dividing (or mitotic) pool, the differentiation (or maturation) pool, and the storage pool; outside the bone marrow are the circulating pool, the vascular marginated pool, and the peripheral tissue pool. Neutrophils transit the circulating pool only during the brief 3- to 6-hour period from bone marrow to tissue. Thus, changes in the WBC count or differential could reflect rapid changes in a relatively small yet highly fluctuant pool.

Estimates suggest that the peripheral blood neutrophil count represents less than 5% of the total neutrophil pool size. Neutrophil distribution studies demonstrate about 1 billion neutrophils per kilogram of body weight, of which about 20% are in the marrow neutrophil precursor pool, 75% are in the marrow storage pool, 3% are in the marginated vascular pool, and 2% are in the circulating blood (Table 46-14). About 1.5 billion neutrophils per kilogram of body weight are produced each day, with a residence time of 9 days in marrow, 3 to 6 hours in blood, and 1 to 4 days in peripheral tissues (see Table 46-14).

Neutrophils are derived from a common stem cell progenitor, which also gives rise to mature erythrocytes, megakaryocytes (and ultimately platelets), eosinophils, basophils, and monocytes (see Fig. 46-1). A variety of recently identified growth factors and cytokines regulate proliferation and differentiation along neutrophilic lineage (see Table 46-1).

TABLE 46–14 Adult Blood Neutrophil Pools and Kinetics

Pool	Definition/Calculation	Mean Pool Size ($\times 10^7$/kg)	95% Limits
Total blood neutrophil pool (TBNP)	All neutrophils in the circulation	70	14-160
Circulating neutrophil pool (CNP)	Blood neutrophil concentration multiplied by blood volume	31	11-46
Marginal neutrophil pool (MNP)	Total blood neutrophil pool less circulating pool (MNP = TBNP − CNP)	39	0-85
Kinetics	**Definition/Calculation**	**Mean Value**	**95% Limits**
$t_{1/2}$ (blood clearance half-time)	Disappearance time of half of the labeled neutrophils from circulation $\frac{0.693 \times \mathrm{TBNP}}{t_{1/2}}$	6.7 hr	4-10 hr
Neutrophil turnover rate (NTR)		163×10^7/kg/day	$50\text{-}340 \times 10^7$/kg/day

Phagocyte Abnormalities

NEUTROPENIA

Neutropenia (<1500/μL) can result from a decline in neutrophil production or from accelerated destruction, as well as from changes in the relative distribution of neutrophils between the circulating pool and the marrow and peripheral tissue pools. Most cases are due to acquired defects, many of which are transient.

Extrinsic Defects of Phagocyte Function

SEPSIS AND POSTINFECTIOUS NEUTROPENIA

Infection is the most common cause of neutropenia in the neonate. Neutropenia is a risk factor for infection and sepsis, but it can also occur as a result of overwhelming sepsis. Neonates are particularly at risk for this complication because their neutrophil storage pools are smaller. Neutrophil counts are sometimes unmeasurable in the peripheral blood if the bone marrow neutrophil pool is exhausted. Both increased vascular neutrophil margination and vascular-to-tissue neutrophil movement are associated with circulating neutropenia during sepsis.

Among hospitalized infants, neonatal sepsis continues to be a major cause of morbidity and mortality. Neonates with very low birthweight (500 to 1000 g) are most vulnerable and are prone to early- and late-onset sepsis. Cytokines such as G-CSF have been used without clear benefit in preventing or treating sepsis in neonates, but they are used more commonly in neutropenic neonates with infection or sepsis. Infusions of intravenous immunoglobulin (see Chapter 39) may also augment IgG levels.[14] Granulocyte transfusions are discussed in Part 2 of this chapter.

NEONATAL ALLOIMMUNE NEUTROPENIA

Neonatal alloimmune neutropenia is estimated to occur in 1 of 2000 live births and is analogous to Rh hemolytic disease of the newborn. The severe neonatal neutropenia is caused by maternal sensitization to paternally inherited human neutrophil antigens, resulting in maternal IgG that crosses the placenta, coats the infant's neutrophils, and causes their destruction by opsonization. Affected newborns often develop fever in the first few days of life with associated cutaneous infections, including umbilical stump infections. Upper and lower respiratory tract infections, otitis media, necrotizing enterocolitis, and sepsis are less common. The onset of symptoms coincides with the severe neutropenia.

Isolated neutropenia (<1000/uL) with normal maternal neutrophil count should trigger suspicion, but nonimmune causes of the neutropenia should be considered as well. Special testing using paternal granulocytes and maternal granulocytes and serum are used to detect maternal antibody to paternal or test panel granulocytes. If there is antibody to a paternal antigen present, the father is then tested serologically and genotypically to determine whether his antigen is homozygous or heterozygous. If the father is homozygous, the risk for future alloimmune neutropenia is 100%. As expected for the half-life of maternal IgG, infant neutrophil counts generally return to normal within the first 1 to 2 months of life. Antibodies to several neutrophil-specific antigens have been detected. Treatment of isoimmune neonatal neutropenia consists of appropriate antibiotics, and sometimes G-CSF or IgG.[22]

AUTOIMMUNE NEUTROPENIA OF INFANCY

Antineutrophil antibodies have been detected in the serum of infants in the first months of life. The incidence of autoimmune neutropenia is estimated at 1 per 100,000 infants. It is most commonly seen between the ages of 5 and 15 months. In primary autoimmune neutropenia (not associated with an underlying disorder), despite neutropenia in the 500 to 1000/μL range, infection is seen in only 12% of patients. A peripheral monocytosis may be present. Autoimmune neutropenia is self-limited, with resolution in the first 2 to 3 years of life. Secondary autoimmune neutropenia is more common in older children and adults and tends to be associated with autoimmune disorders, infections, and drugs. If bone marrow analysis is done, there may be a paucity of neutrophils and myeloid progenitor cells, depending on the specificity of the antibody for mature or progenitor cell antigens. The overall bone marrow cellularity may be normal or hypercellular.

The autoantibodies are directed against human neutrophil antigens, which are usually glycosylated isoforms of FcγRIIIb (or CD 16b). Less commonly, the antibodies are directed against adhesion glycoproteins of the CD 11/Cd 18 (HNA-4a, HNA-4b) complex. Qualitative and quantitative defects in neutrophils have been noted. Qualitative defects may explain why a subset of patients with autoimmune neutropenia do develop serious infections.

A variety of assays (e.g., opsonization and immunochemical and direct antibody binding) have been used to detect circulating and bound neutrophil-specific antibodies. The degree of neutropenia is related to the specificity of the antibody as well as its titer and affinity.

Therapy for autoimmune neutropenia depends on the severity of the neutropenia-associated symptoms (e.g., fever and infection). Often no treatment is needed. Antibiotics, with or without the addition of G-CSF or intravenous γ-globulin, are sometimes necessary. Corticosteroid use is reported in the older literature, but this treatment is less frequent now that less toxic therapies are available.[16]

DRUG-INDUCED NEUTROPENIA

An enormous number of agents have been implicated as causes of neutropenia (Box 46-5). The mechanisms could involve direct bone marrow suppression or immune-mediated destruction (see "Autoimmune Neutropenia of Infancy," previously). Anti-inflammatory drugs, semisynthetic penicillins, antiseizure medications, and a host of others are commonly seen in the newborn nursery. Recovery from marrow toxic effects generally begins within several days after the offending agent is discontinued. As with recovery from chemotherapy-induced neutropenia, recovery of peripheral neutrophil counts is ushered in by a rise in circulating monocytes and immature neutrophils in the peripheral blood.

IDIOPATHIC NEUTROPENIA OF INFANTS WITH VERY LOW BIRTHWEIGHT

In 1998, Juul's group reported their evaluation of four infants with very low birthweight who had neutropenia from, or shortly following, delivery and lasting for 1 to 9 weeks.[41] Maternal antineutrophil antibody studies were negative. All patients responded to a 3-day trial of G-CSF by transiently normalizing blood neutrophil counts, and all four infants experienced complete resolution of neutropenia by week 9.

THERAPEUTIC USES OF G-CSF AND GM-CSF

The cytokines G-CSF and GM-CSF are members of a family of hematopoietic growth factors that stimulate production of mature WBCs in the bone marrow. These two cytokines also enhance neutrophil and monocyte functions, such as neutrophil oxidative metabolism, chemotaxis, and phagocytosis. Both are normally present at low concentrations in serum. G-CSF levels are about threefold higher in the cord blood of premature infants than in term infants in the first 3 days of life.[13] G-CSF levels peak at 7 hours of life, followed by a rise in the neutrophil count at about 13 hours of life.

When normal adults are exposed to an infectious challenge, G-CSF levels rise, and peripheral neutrophilia follows. GM-CSF levels, on the other hand, remain steady. Whether preterm and full-term infants are capable of mounting an appropriate cytokine response to infection or sepsis and whether neonatal cells respond adequately to cytokines are still controversial issues. Although neonatal neutrophil GM-CSF and G-CSF receptors are quantitatively similar and share comparable binding affinities with those on adult cells, in vitro studies of adult and neonatal mononuclear cells demonstrated an eightfold lower cytokine response to mitogen stimulation by the neonatal cells. Regardless, some recent studies have documented an increase in serum G-CSF levels in full-term and preterm infants with bacterial infection compared with healthy term infants.

Some clinical trials using pharmacologic doses of G-CSF and GM-CSF have shown benefit in patients with acquired and congenital neutropenia by reducing infectious morbidity and mortality and improving quality of life. The utility of these growth factors in the treatment and prevention of sepsis in non-neutropenic infants, on the other hand, has not been clearly demonstrated.[6]

Inherited Disorders Associated with Neutropenia

SEVERE CONGENITAL NEUTROPENIA

Severe congenital neutropenia is a heterogeneous group of disorders first described in a large, consanguineous family by Swedish physician Rolf Kostmann. In the first several months of life, infants manifest recurrent severe infections (e.g., omphalitis, skin abscesses, respiratory tract infections, and otitis media) and a marked reduction or absence of circulating neutrophils. Bone marrow examination reveals a paucity of myeloid cells and an arrest at the promyelocyte or myelocyte stage. Staphylococcal and streptococcal infections are common, whereas yeast, fungal, and parasitic infections are rare.[83] According to the Severe Chronic Neutropenia International Registry data, mortality from sepsis is 0.4% per year in those who respond to G-CSF and 1.4% per year in those whose G-CSF response is less optimum.[83] Patients who survive through early childhood develop myelodysplastic syndrome and acute myelogenous leukemia at 10 years.[71]

Severe congenital neutropenia exhibits multiple patterns of inheritance, including autosomal dominant, autosomal recessive, X-linked, and sporadic. Most cases are caused by heterozygous missense mutations in the gene encoding neutrophil elastase (*ELA2*), a serine protease present in neutrophil and monocyte granules.[80] Emerging evidence suggests that these mutations trigger the unfolded protein response, leading to increased apoptosis of granulocyte progenitors.[80] Homozygous mutations of *HAX1* are associated with the autosomal recessive variant of severe congenital neutropenia. *HAX1* is a member of the anti-apoptotic *BCL2* gene family, suggesting that increased apoptosis is the mechanism underlying this form of severe congenital neutropenia. There are three case reports of patients with severe congenital neutropenia who have germline heterozygous mutations in the G-CSF receptor gene (*CSFR3*).[7] Heterozygous germline mutations of *GFI1*,

which encodes a transcriptional repressor, have been reported in families with persistent neutropenia and lymphopenia.[7] An X-linked form of severe congenital neutropenia has been linked to gain-of-function mutations in *WAS*, the gene mutated in Wiscott-Aldrich syndrome and X-linked thrombocytopenia (see later).

Treatment with human recombinant G-CSF markedly reduces the number and degree of serious infections and corrects circulating neutrophil levels to normal in many patients. Some patients require high doses for response. A subset of patients with underlying defects in neutrophil function remain at risk for sepsis even when the ANC is increased. Hematopoietic stem cell transplantation from an HLA-matched, unaffected sibling should be considered for patients with severe congenital neutropenia, especially those who respond poorly to G-CSF.

SHWACHMAN-DIAMOND SYNDROME

See also Chapter 47.

This rare syndrome of neutropenia ($<500/\mu L$) associated with pancreatic insufficiency and metaphyseal dysplasia is inherited in an autosomal recessive pattern. A variety of physical abnormalities, including short stature, are common. Neutrophil counts generally are less than 500/μL, and moderate thrombocytopenia and anemia are common. Many patients have qualitative neutrophil defects. Defects in B, T, and NK lymphocytes have also been described. Severe, recurrent infections with *Staphylococcus* species, *Haemophilus* species, and gram-negative rods, as well as steatorrhea, are seen within the first 10 years of life. Transformation to acute leukemia occurs at a high rate. Serum trypsinogen is abnormal; sweat chloride testing is normal. The disease has been linked to homozygous mutations in the *SBDS* gene on chromosome 7q11. The function of this gene is unknown, but it might participate in RNA metabolism. The gene defect in most cases of Shwachman-Diamond syndrome is a conversion mutation from a pseudogene.[8] The etiology of the neutropenia is not understood, although it often responds to administration of G-CSF. Hematopoietic stem cell transplantation has been reported to have an increased incidence of transplant-related complications.

MYELOKATHEXIS

Another rare disorder with severe congenital neutropenia, severe and recurrent infections, and dysmorphic myeloid elements in the bone marrow, myelokathexis is more common in females and may have autosomal dominant inheritance. It may be part of the WHIM syndrome (warts, hypogammaglobulinemia, infections, myelokathexis).[51]

CONGENITAL DYSGRANULOPOIETIC NEUTROPENIA

This disease with severe congenital neutropenia, severe infections, and defects in primary and secondary myeloid granules is an autosomal recessive disorder.[44]

P14 DEFICIENCY

This disorder of congenital neutropenia, recurrent respiratory infections, reduced cytotoxic T-cell function, low IgM, short stature, partial albinism, and coarse facial features is responsive to G-CSF. P14, involved in MAP kinase signaling, is deficient in these patients.[9]

CYCLIC NEUTROPENIA

Children with cyclic neutropenia often display recurrent fevers and bacterial infections (e.g., stomatitis and pharyngitis), with cyclical patterns at intervals of 2 to 5 weeks. The cyclic nature of the neutropenia correlates precisely with the presence and severity of the infections. Individual patients maintain constant cycle times. Diagnosis is based on frequent CBCs (two to three times weekly) over a 6-week period demonstrating a cyclic rise and fall of the ANC. Platelet count and monocytes often rise and fall paradoxically with the ANC. Bone marrow examination reveals hypocellularity of the myeloid lineage with myelocyte arrest during times of peripheral neutropenia. Based on studies in humans and in the gray collie dog (an animal model), a regulatory defect at the level of the stem cell has been hypothesized.

This disorder, like severe congenital neutropenia, has been linked to single-base substitutions in the gene encoding neutrophil elastase.[40] It is unclear why these mutations affect the clocklike timing of hematopoiesis. Therapy consists of administering prophylactic antibiotics and G-CSF.

CARTILAGE-HAIR HYPOPLASIA

Cartilage-hair hypoplasia is a rare autosomal recessive disorder characterized by short-limbed dwarfism, fine hair, hyperextensible digits, increased susceptibility to infection, lymphopenia, and chronic neutropenia. Cellular immunity is abnormal. Cartilage-hair hypoplasia is an autosomal recessive disease caused by mutations in *RMRP*, a noncoding RNA gene involved in mitochondrial DNA replication, ribosome biogenesis, and ribosomal RNA processing.[7] The cellular defects have been treated with hematopoietic stem cell transplantation.

DYSKERATOSIS CONGENITA

Dyskeratosis congenita is characterized by neutropenia (and other cytopenias), abnormal skin pigmentation, nail dystrophy, and mucosal leukoplakia. Other features include immunodeficiency, fragile bones, tooth decay, short stature, alopecia or premature graying, gonadal hypoplasia, urethral abnormalities, pulmonary fibrosis, liver cirrhosis, esophageal strictures, mental retardation, and a predisposition to cancers of the skin, gastrointestinal tract, and other sites.

Impaired telomere maintenance has been implicated in the pathogenesis of dyskeratosis congenita. It is hypothesized that the clinical manifestations of dyskeratosis congenita, which develop at a variable rate during childhood, are caused by excessive telomere shortening in stem cells within rapidly dividing tissues (e.g., skin or bone marrow). Autosomal dominant dyskeratosis congenita has been linked to mutations in either the telomerase RNA (*TERC*) gene or telomerase catalytic subunit (*TERT*) gene, and the X-linked form of the disease is caused by mutations in *DKC1*, which encodes a protein implicated in telomerase RNA processing or stabilization. Mutations in *DKC1* have also been identified in Hoyeraal-Hreidarsson syndrome, a condition marked by prenatal growth restriction, pancytopenia, cerebellar atrophy, abnormal myelination of cerebral white matter, and hypoplasia of the corpus callosum. Hoyeraal-Hreidarsson syndrome is considered a severe variant of X-linked dyskeratosis congenita. Other telomere maintenance genes mutated in some cases of dyskeratosis congenita include *NOP10, TINF2*, and *NHP2*.[7]

Hematopoietic stem cell transplantation is the only cure for patients who develop severe bone marrow complications of dyskeratosis congenita. However, patients with dyskeratosis congenita who undergo conventional transplantation do poorly because of a high incidence of early and late transplant-related complications, including severe mucositis, sepsis, hepatic veno-occlusive disease, microangiopathic hemolytic anemia, and pulmonary fibrosis. Recent studies suggest that nonmyeloablative transplant conditioning regimens afford better outcomes in these patients.

RETICULAR DYSGENESIS

This is a rare syndrome of lymphoid hypoplasia, thymic aplasia, and agranulocytosis with normal bone marrow megakaryocyte and erythroid precursors. Patients have low serum IgM and IgA levels and die in infancy without hematopoietic stem cell transplantation. There is a maturation arrest in the myeloid lineage and also a global impairment of lymphoid maturation leading to severe reduction in both B- and T-cell numbers. The mitochondrial energy metabolism enzyme adenylate kinase 2 (AK2) is mutated in individuals with reticular dysgenesis.[65] Hematopoietic stem cell transplantation is the only curative treatment.

Congenital Neutropenia with Inborn Errors of Metabolism

GLYCOGEN STORAGE DISEASE TYPE 1 (VON GIERKE DISEASE)

Patients with type 1b have neutropenia, but those with type 1c also have a qualitative neutrophil defect that is associated with an increased susceptibility to infections. G-CSF has successfully decreased infection rates in patients with type 1b.[48]

COBALAMIN AND FOLATE DEFICIENCIES

Whether nutritional or due to an inherited disorder affecting vitamin B_{12} or folate metabolism, mild neutropenia is associated with the megaloblastic anemia of cobalamin and folate deficiencies.

Neutropenia Associated with Agammaglobulinemia

In this primary immunodeficiency disorder, severe immunodeficiency is accompanied by neutropenia. Hematopoietic stem cell transplantation can be life-saving.

NEUTROPHILIA

Neutrophilia is the specific elevation of the ANC more than 2 standard deviations above the mean (Box 46-6).

Intrinsic Defects that Cause Neutrophilia

LEUKEMOID REACTION

Newborns sometimes mount an exaggerated response to infection. As in older children, the circulating neutrophil count increases, and a left shift occurs (band forms, myelocytes, and metamyelocytes increase in the peripheral circulation). A significant increase in early neutrophil precursors in the peripheral blood, as well as an increase in the white blood cell count (generally exceeding 50,000/μL), is considered a leukemoid reaction. A normal newborn in the first 2 days of life displays a neutrophil-to-band ratio greater than 7:1 (see Table 46-13). A leukemoid reaction associated with severe infection in the newborn often is accompanied by cytoplasmic vacuoles within the neutrophil and by the appearance of toxic granulations. Infants with Down syndrome can have a type of leukemoid reaction (see "Down Syndrome," later). A rare, autosomal dominant hereditary neutrophilia has been described.[39]

A prospective study of all patients admitted to the neonatal intensive care unit at the University of Florida during a 12-month period identified 9 of 707 patients (1.3%) with a transient leukemoid reaction.[15] Of these 9 patients, 7 were identified in the first 4 days of life, and 1 presented on day 9 and 1 at day 25 of life. One infant had Down syndrome. Maternal betamethasone treatment was associated in 4 cases. Hyperviscosity and congenital infection were excluded in all 9. The duration of the reaction ranged from 5 to 32 days, the longest being in the infant with trisomy 21.

DOWN SYNDROME

About 10% of infants who have Down syndrome develop transient myeloproliferative disorder. This process also sometimes occurs in a phenotypically normal child with trisomy 21 mosaicism, including an isolated clone of trisomy 21 bone marrow cells. Transient myeloproliferative disorder is characterized by the presence of megakaryoblasts in the peripheral blood, variable thrombocytopenia, and hepatosplenomegaly. Abnormalities of all three hematopoietic cell lineages have been described. Additional cytogenetic abnormalities might be present in the blasts. In most cases, the reaction is transient and resolves within the first 3 months of life, although it can be life-threatening or fatal.[25] Occasionally, it reappears.

By some estimates, up to 30% of infants with Down syndrome and transient myeloproliferative disorder develop acute megakaryoblastic leukemia (AMKL) in the first 4 years of life, suggesting that transient myeloproliferative disorder is a preleukemic state. Somatic mutations in *GATA1* have been reported in nearly all cases of transient myeloproliferative disorder and Down syndrome AMKL but not in other forms of leukemia. In addition, several groups of investigators have found identical *GATA1* mutations in the transient myeloproliferative disorder and AMKL blasts of patients for whom sequential samples were available. Together, these findings demonstrate that the development of a *GATA1* mutation is an early event in Down syndrome myeloid leukemogenesis.[35]

Management of affected infants is controversial. Most pediatric oncologists adopt a wait-and-see approach in managing these leukemoid reactions, regardless of chromosomal abnormalities. Infants with organ infiltration or a severe course are more likely to receive treatment with chemotherapy.

Disorders of Phagocyte Function

ADHESION DISORDERS

Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency is a rare group of autosomal recessive disorders characterized by persistent leukocytosis, delayed separation of the umbilical cord, and recurrent infections.[21] Leukocyte adhesion deficiency type I is characterized by the impairment of respiratory burst generation of complement-opsonized microorganisms and associated with defects in neutrophil adhesion and chemotaxis (Fig. 46-9). The clinical picture varies depending on the relative deficiency of CD18. CD18 is the β_2-subunit of cell surface leukocyte integrins. These molecules are involved in adherence, chemotaxis, C3bi-mediated ingestion, degranulation, and neutrophil respiratory burst activation. Leukocyte adhesion deficiency should be suspected in any infant who has unusually severe bacterial infections accompanied by normal to increased blood leukocyte counts. There is a striking absence of pus at the site of infection because neutrophils do

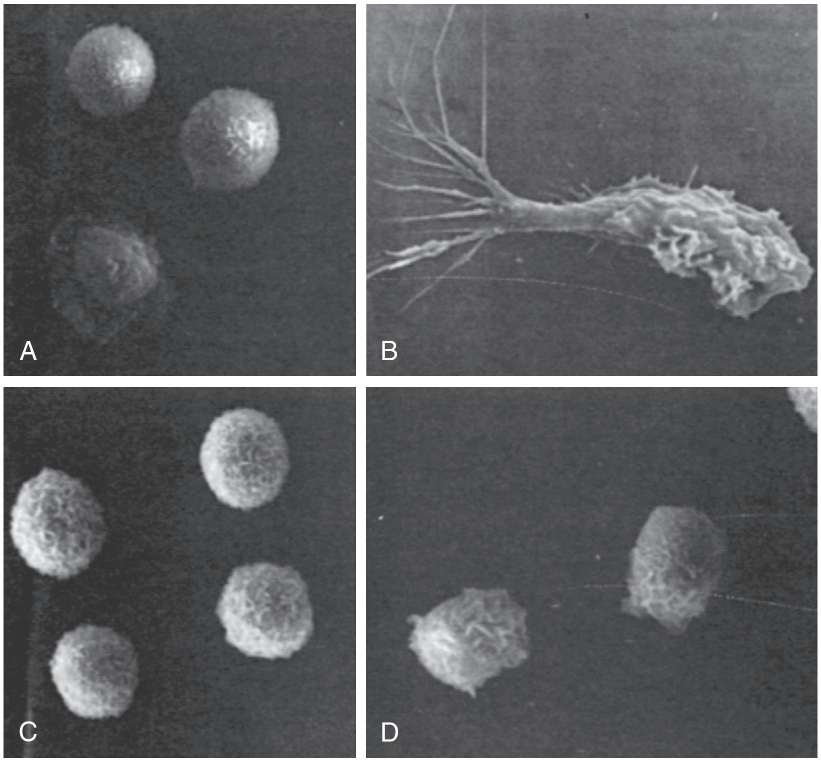

Figure 46–9. Attachment and spread of leukocyte adhesion deficiency (LAD) (**A**) and control (**B**) neutrophils through cell surface integrins, as visualized through scanning electron microscopy. Orientation and movement of LAD (**C**) and control (**D**) neutrophils to a chemotactic gradient (from the right), as visualized by means of scanning microscopy. *(Adapted from Anderson D, et al: Abnormalities of polymorphonuclear leukocyte function associated with a heritable deficiency of high-molecular-weight surface glycoproteins (GP 138): common relationship to diminished cell adherence,* J Clin Invest *74:536, 1985.)*

not migrate from the vasculature to sites of inflammation within tissues.

Diagnosis of leukocyte adhesion deficiency type I is made, generally by flow cytometric analysis, by demonstrating a severe deficiency of the β_2-subunit of neutrophil integrins (usually 0% to 10%). Carriers can be identified by the expression of an about 50% normal β_2-integrin level on circulating neutrophils. Therapy for patients with leukocyte adhesion deficiency type I depends on the clinical severity. Patients with a moderately severe clinical phenotype can be aggressively managed with antibiotics. However, patients with a severe phenotype often succumb to overwhelming infection in the first or second year of life. Hematopoietic stem cell transplantation is indicated for patients with severe leukocyte adhesion deficiency type I.[21]

Leukocyte Adhesion Deficiency Type II (Rombam-Hasharon Syndrome)

In addition to persistent leukocytosis and recurrent bacterial infections, this autosomal recessive clinical syndrome has been described in a few patients in Israel to include short stature, severe mental retardation, and the hh (Bombay) RBC phenotype.[21] Neutrophils from these patients exhibited markedly diminished chemotaxis in vitro, although the neutrophils displayed normal levels of CD18 and were able to phagocytose serum-opsonized particles. The molecular defect in these patients is a defect of fucosyl transferase, the enzyme responsible for carbohydrate linkages associated with the AB blood groups, specifically the sialyl-Lewis X structure. This has importance for neutrophil function because the sialyl-Lewis X structure is necessary for the formation of the neutrophil cell surface ligand recognized by the endothelial cell surface E-selectin and P-selectin receptors.

Neutrophil Actin Dysfunction

Neutrophil actin dysfunction is an autosomal recessive disorder with markedly diminished chemotaxis in vitro and a diminished ability to ingest opsonized particles.[21] The neutrophils exhibit dysfunctional actin polymerization in vitro. The patient first described with this disorder died, and subsequently the neutrophils of his parents and sister were shown to have half the actin polymerizability in vitro with normal in vivo function.[75]

CHEMOTAXIS DISORDERS

Newborns, particularly premature infants, are at increased risk for severe bacterial infections. Neonates' neutrophils have a variety of disorders associated with immune surveillance and neutrophil-mediated immune function, but the particular defects and mechanistic bases thereof are not clear. For example, neonatal neutrophils display reduced chemotaxis in vitro compared with adult neutrophils. This could result from diminished augmentation of β_2-integrin (i.e., Mac-1) upregulation after exposure to chemotactic stimuli. That is, neutrophils from fetuses and from preterm and term infants display about 50% levels of Mac-1 compared with neutrophils from adults. After exposure to chemotactic mediators (e.g., bacterial extracts), the intracellular membrane-bound pool of Mac-1 is inappropriately mobilized in these neutrophils compared with neutrophils from adults.[76]

INGESTION AND DEGRANULATION DISORDERS

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a rare autosomal recessive disorder characterized by oculocutaneous albinism, progressive neuropathy, platelet dysfunction, frequent neutropenia, and progression to an accelerated phase and lymphoma-like syndrome (see also Chapter 52). The responsible gene has been cloned, and its product functions as a vacuolar sorting protein. Giant cytoplasmic granules and giant organelles are seen in many cells throughout the body because trafficking of granular proteins and organelles is defective. The syndrome affects neutrophil, platelet, and lymphocyte function. Neutrophils from affected patients demonstrate abnormal adherence and chemotaxis, delayed granulation, and diminished killing of ingested microorganisms. Patients with this disorder are unduly susceptible to bacterial infections. Most patients also undergo an accelerated phase, marked by lymphohistiocytic infiltration of multiple organs. This lymphoproliferative syndrome appears to result principally from a lack of natural killer cell function. Death often occurs in the first decade from infection, bleeding, or development of the accelerated phase. Hematopoietic stem cell transplantation can be used to treat the hematologic complications of Chédiak-Higashi syndrome.

OXIDATIVE KILLING DISORDERS

Chronic Granulomatous Disease

Chronic granulomatous disease is a rare (about 1 in 200,000), genetically heterogeneous disorder characterized by inherited defects in the neutrophil respiratory burst generated by the reduced NADPH oxidase enzyme.[76] Affected patients develop severe recurrent bacterial and fungal infections, often caused by organisms not ordinarily considered pathogens (e.g., *Aspergillus* species). Most patients manifest symptoms within the first year of life (Box 46-7). Inadequate neutrophil killing or ingestion is associated with a chronic inflammatory response that culminates in the formation of macrophage-containing granulomas throughout the gastrointestinal and urinary tracts. Chronic granulomatous disease manifests as a clinically heterogeneous disorder in which a minority of patients have a milder clinical course.[76]

This disorder, first described in 1957, is associated with absent or markedly reduced respiratory burst oxidase (phagocyte NADPH oxidase, or PHOX) activity in neutrophils, monocytes, and macrophages.[76] Because four distinct gene products are required for functional NADPH oxidase activity, defects in any one of these components can lead to this disorder. Chronic granulomatous disease is usually X-linked in inheritance, associated with the gp91 protein, gp91-PHOX, but autosomal recessive forms are associated with defects in CYBA, NCFI, and other PHOX proteins (as shown in Table 46-15). Diagnosis of chronic granulomatous disease was classically made using the nitroblue-tetrazolium test, in which reduction of nitroblue-tetrazolium by superoxide free radical formation does not occur in patients. Currently dihydrorhodamine-stained neutrophils from a whole blood sample are incubated and stimulated to produce superoxide radicals (or not) to reduce dihydrorhodamine. A cytochrome C reduction assay can estimate the amount of superoxide free radical a patient can produce. Genetic analysis of affected patients can identify the specific genetic defect.[56] Therapy involves prophylactic antibiotics and antifungal agents. Recombinant interferon-γ-1b prophylaxis has also been effective in reducing the incidence of infections. γ-Retroviral gene therapy has been reported in some patients with chronic granulomatous disease and has been associated with benefit in a minority but also some severe toxicities, including death. Hematopoietic stem cell

BOX 46–7 Clinical Presentation of Chronic Granulomatous Disease*

CHRONIC CONDITIONS
Lymphadenopathy
Hepatomegaly

transplantation could also correct the defect in chronic granulomatous disease.

Myeloperoxidase Deficiency

Myeloperoxidase deficiency is the most common inherited disorder of neutrophils, with complete deficiency found in about 1 in 4000 persons and partial deficiency observed in 1 in 2000. However, most affected persons are notable for lack of any symptoms. The classic presentation in the subset of patients is immunodeficiency and infection with *Candida albicans*. It can mimic chronic granulomatous disease in certain screening tests.

HEMOSTASIS

Tissue injury triggers a number of immediate host responses whose goal is to maintain blood vessel integrity while more permanent repair processes are underway. Participants in the human hemostatic mechanism include the blood vessels, platelets, procoagulant and anticoagulant proteins, and fibrinolytic system. An abnormality in any component can disrupt the critical balance and result in excessive thrombosis or bleeding. Although much remains to be discovered, many alterations in the hemostatic mechanism have been described in the healthy fetus and newborn, and because the normal fetus and newborn do not suffer from excessive bleeding or thrombosis, these differences must be considered physiologic.

The first half of this section provides an overview of hemostasis, including a discussion of the known physiologic differences in hemostasis in the fetus and newborn. The second half examines the hemorrhagic and thrombotic disorders that commonly and sometimes almost exclusively occur in the neonate.

Components of Hemostasis

BLOOD VESSELS

The endothelial cell lining of blood vessels provides a structural interface between the blood and the subendothelial matrix. In its uninjured, inactive state, it presents an antithrombotic surface to which platelets do not adhere. Endothelial cell products with antithrombogenic properties include prostacyclin (PGI_2), the lipoxygenase pathway product 13-hydroxyoctadecadienoic acid, and heparan sulfate proteoglycans. Nitric oxide is produced by the intact endothelium and has vascular relaxation activity and contributes to inhibition of platelet adhesion and aggregation.

After injury, the smooth muscle layer of involved arterioles or venules contracts, resulting in localized vascular constriction and reduced blood loss from the injured site. When the endothelial surface is disrupted, thrombotic subendothelial substances are exposed to blood. Alternatively, exposure of the endothelium to various inflammatory or immune mediators as a result of systemic illness, infection, or tissue injury substantially alters the endothelium to an activated state. The vascular endothelium then becomes a contact point for adhesion and aggregation of activated platelets and leukocytes and for deposition of the coagulation proteins. Tissue factor can form a complex with circulating coagulation factor VIIa to initiate the fluid phase of coagulation.

The circulating procoagulant molecule thrombin also participates in anticoagulant processes by its association with thrombomodulin on the endothelial cell surface to promote activation of protein C (see “Physiologic Anticoagulation Strategies and Proteins,” later). Fibrinolytic activities of cultured endothelial cells include production of urokinase and tissue plasminogen activator (t-PA). There are binding sites for plasminogen and t-PA on the cell surface.

Genetic and environmental factors influence alterations in the human vascular endothelium, which occur over a lifetime. Many of these changes enhance the thrombotic potential of the vasculature. Little is known about the functional differences between newborn and adult endothelium.

PLATELETS, ENDOTHELIUM, AND VON WILLEBRAND FACTOR

Platelets participate in the first phase of hemostasis, during which a platelet plug forms at the site of blood vessel injury. Platelets limit loss at the site of endothelial disruption within injured blood vessels, and they also provide a framework to facilitate fibrin clot formation by components of the plasma phase of coagulation. Platelets circulate as smooth discs, but on exposure to agonists released in response to vascular injury or endothelial activation, they become activated, adhere to the site of disrupted endothelium, aggregate, release their granule contents, and promote the generation of thrombin. The most active physiologic platelet activators are thrombin and collagen. Adenosine diphosphate and epinephrine are weaker agonists. Thrombin can cleave protease-activated receptors PAR-1 and PAR-4, members of the G-protein protease-activated receptor family of transmembrane signaling proteases. This appears to be the major physiologic activation process for platelets. Platelets also become activated through the collagen receptor glyoprotein (GP) IV and adhere to the subendothelium via collagen receptor GP Ia/IIa.

Activated platelets undergo shape change to extend adhesive pseudopods. Platelets adhere to von Willebrand factor (vWF) in the subendothelium through their GP Ib/IX/V surface glycoprotein receptor. Platelet activation also allows a conformational change in, and surface expression of, the glycoprotein receptor GP IIb/IIIa, which binds fibrinogen (as well as some vWF) and results in platelet aggregation. Additionally, the cytosolic part of GP IIb/IIIa in activated platelets binds to their cytoskeleton and participates in platelet shape changes and clot retraction. The resultant platelet plug functions not only as a physical barrier at the site of a break in the endothelium but also as an initiator for thrombin production and rapid formation of a localized fibrin clot. Activated platelets degranulate and secrete many substances that promote vasoconstriction, endothelial adhesion, platelet activation and recruitment, platelet aggregation, and thrombin formation. The exposure of surface prothrombotic phospholipids such as phosphatidylserine promotes the localized surface formation of procoagulant enzyme complexes. Coagulation factor V and fibrinogen are released by activated platelets, and the phospholipid of the platelet membrane assists in the formation of complexes of coagulation factors and calcium, so that fibrin clot formation proceeds rapidly and efficiently. Platelet function, physiologic alterations in the newborn, and qualitative and quantitative abnormalities of platelet function are discussed later.

vWF is a multimeric glycoprotein synthesized by megakaryocytes and endothelial cells that functions in platelet adhesion (through GP Ib/IX/V) and aggregation (through GP IIb/IIIa) (Fig. 46-10). It is secreted by activated platelets, is found in the subendothelial matrix, and also circulates in plasma as a carrier for coagulation factor VIII. vWF is a highly multimeric glycoprotein. The largest multimers are the most functional in platelet adhesion and aggregation activities. Platelet-vWF-fibrinogen interactions are measured most commonly by the platelet function screening tests such as the PFA-100 (Dade-Behring, Deerfield, IL). Bleeding time testing is generally not done in neonates (see "Laboratory Testing of the Neonatal Hemostatic System," later).

COAGULATION FACTORS

Coagulation proceeds through the sequential activation of zymogens (inactive proenzymes) to enzymes and the assembly of complexes of enzymes in association with cofactors, calcium, and phospholipids that produce a robust amount of thrombin and a strong fibrin clot. Effective localization of blood clot formation is necessary so that hemostasis is achieved and yet systemic thrombosis is avoided. The cellular participants in hemostasis, as well as most of the circulating procoagulant proteins, normally exist in their inactive states. The plasma concentrations of the zymogens are low enough that spontaneous activation is rare. The efficiency of the activation reactions improves enormously when the proteins are brought into close approximation with their activating enzymes and cofactors through the formation of calcium-containing complexes on a cellular phospholipid membrane.

In 1964, the coagulation cascade-waterfall hypothesis was introduced (Fig. 46-11). This theory proposed two pathways leading to activation of factor X, which then combined with cofactor Va to cleave prothrombin to thrombin. Thrombin cleaved fibrinogen to fibrin, leading to eventual fibrin clot formation. According to this theory, coagulation could be initiated either by the intrinsic pathway, so named because all the necessary components existed in plasma, or by the extrinsic pathway, which required addition of tissue factor. The extrinsic

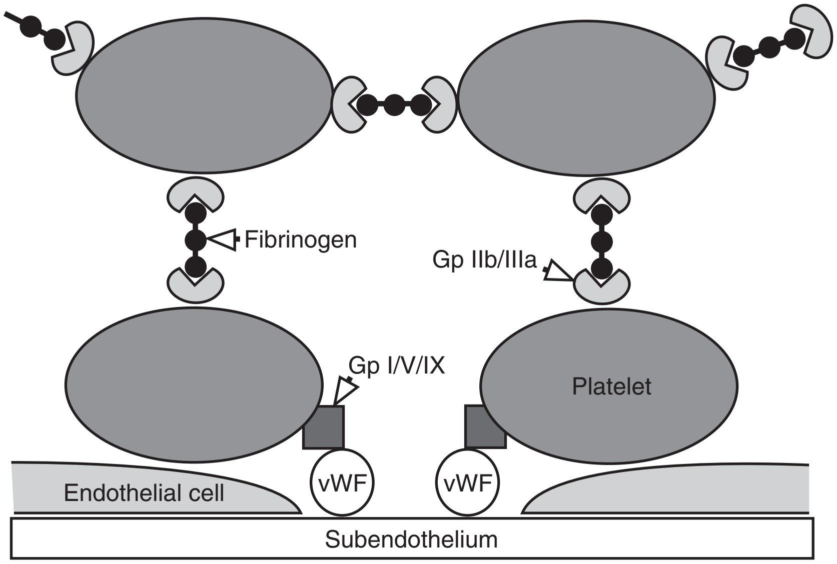

Figure 46–10. Schematic representation of the interaction of platelets with the subendothelium (see text for details). Gp, glycoprotein; vWF, von Willebrand factor.

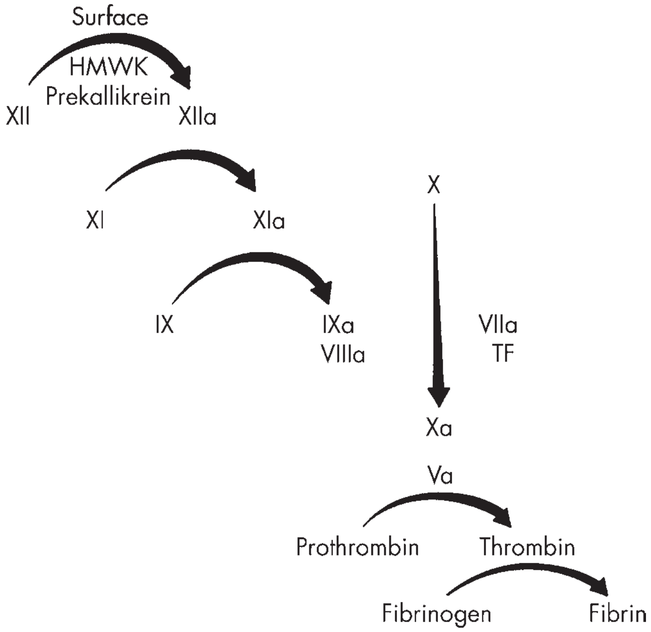

Figure 46–11. The cascade-waterfall hypothesis of blood coagulation. In this scheme, coagulation may be initiated by the extrinsic or intrinsic pathway, either of which can lead to thrombin-mediated formation of a fibrin clot via a common pathway involving factor Xa, factor Va, and phospholipids. HMWK, high-molecular-weight kallikrein; TF, tissue factor.

and intrinsic pathways could be tested separately by the prothrombin time (PT) and partial thromboplastin time (PTT) assays, respectively. The PT and activated partial thromboplastin time (aPTT) tests have proved invaluable for evaluation of coagulation factor deficiencies; however, a number of clinical and laboratory observations could not be explained by the cascade-waterfall hypothesis. A physiologic activator of the intrinsic pathway's contact activators has not been found, and people who are deficient in these contact activation factors, factor XI, prekallikrein, or high-molecular-weight kininogen, have prolonged aPTT assay results but do not bleed abnormally. Patients with severe hemophilia A (factor VIII deficiency) or hemophilia B (factor IX deficiency) have serious clinical bleeding abnormalities. In contrast, those with deficiency of another intrinsic pathway member, factor XI, have a milder clinical course. Severe factor VII deficiency (extrinsic pathway) results in hemorrhagic abnormalities.

In 1991, Gailani and associates[33a] proposed the revised hypothesis of coagulation (Fig. 46-12). Clotting is initiated when subendothelial tissue factor is exposed to circulating factor VII or VIIa. The factor VIIa-tissue factor complex associates with calcium on a phospholipid surface to form the *extrinsic tenase complex*, which activates factor X and factor IX. Some of the factor Xa complexes with cofactor Va, calcium, and phospholipid (the *prothrombinase complex*) and cleaves prothrombin to thrombin. This initial thrombin activates platelets. Factor IXa, in combination with cofactor VIIIa, calcium, and a phospholipid membrane, forms the *intrinsic tenase complex*, activates additional factor X, and produces more thrombin. This thrombin activates factor XI, which activates factor IX and then promotes robust thrombin production through the intrinsic tenase complex, followed by the prothrombinase complex. Thrombin can cleave fibrinogen to fibrin, leading to production of a fibrin clot. Fibrin monomers spontaneously polymerize into strands, but covalent bonding of the strands into a stable clot is accomplished by the transglutaminase, factor XIII. Factor XIII is activated by thrombin. In addition, premature breakdown of the clot is prevented by the thrombin-activated fibrinolysis inhibitor. When coagulation factors or cofactors are defective or deficient, less thrombin is generated. This affects the quality as well as the quantity of fibrin clot formation.

Interestingly, thrombin also promotes anticoagulant and antifibrinolytic processes.

PHYSIOLOGIC ANTICOAGULANT STRATEGIES AND PROTEINS

Balancing the efficient, localized formation of clot at a site of injury are the anticoagulant complexes, which bind to endothelial cells and efficiently inactivate clotting factors to prevent

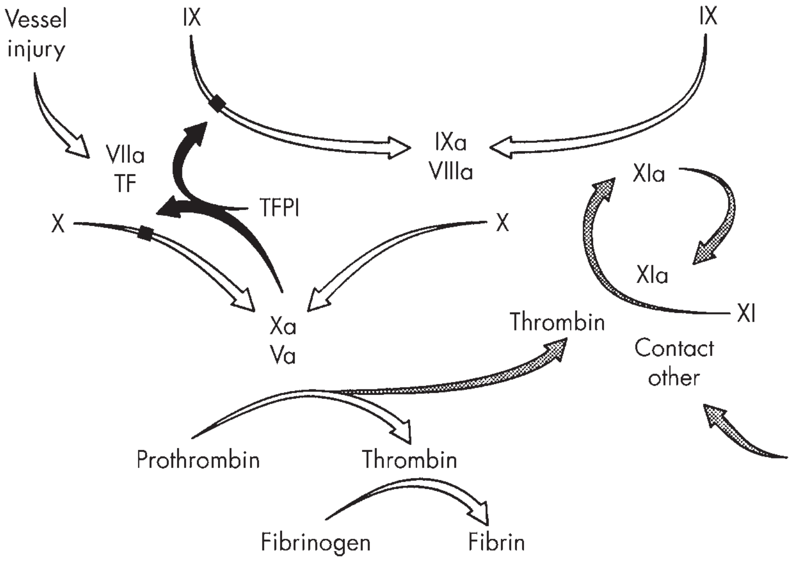

Figure 46–12. Revised hypothesis of blood coagulation, in which coagulation is initiated by factor VIIa- and tissue factor (TF)-mediated activation of factors IX and X, sustained through the participation of factors VIIIa and IXa, and consolidated by factor XIa. Tissue factor pathway inhibitor (TFPI) inhibits factor Xa, and in a factor Xa-dependent fashion, feeds back and inhibits the factor VIIa-tissue factor complex.

excessive coagulation and systemic thrombosis. In pathologic states, diffuse and unregulated activation of the hemostasis can occur, resulting in systemic thrombosis. Normally, some activated coagulant factors drift away from the coagulation complexes and are diluted in the bloodstream. Clotting factors are proteolytically degraded. In addition to nonspecific limitations of clot formation, anticoagulant systems also prevent excessive clot formation. Thrombin is a necessary component of clot formation, but it also serves to localize and limit the process by complexing with anticoagulant proteins and the fibrinolytic system to localize and enhance the efficiency of the anticoagulation and fibrinolytic reactions.

One inhibitor of coagulation, tissue factor pathway inhibitor, is present at low concentration in the plasma and is stored in the endothelium. Factor Xa can combine with tissue factor pathway inhibitor and become inhibited. Additionally, the tissue factor pathway inhibitor–factor Xa complex produces feedback inhibition of the factor VIIa–tissue factor complex. Tissue factor pathway inhibitor is produced in the microvascular endothelium and its release into plasma is enhanced by heparin.

A second coagulation inhibitor is antithrombin, formerly referred to as antithrombin III. Antithrombin inactivates a number of coagulation proteases, the most important of which is factor IIa (thrombin), as well as factors XIa, Xa, and IXa. The anticoagulant drug heparin and naturally occurring endothelial cell surface heparan sulfate greatly accelerate the activity of antithrombin. The anticoagulant effect of heparin is largely due to enhancement of inhibition of thrombin and factor Xa through interactions with a critical pentasaccharide region.

Thrombin also binds thrombomodulin on the endothelial surface, promoting protein C activation. Activated protein C, with its cofactor protein S, in the presence of calcium and phospholipids, proteolytically inactivates factors Va and VIIIa. Qualitative or quantitative defects in the anticoagulant proteins or in their ability to inactivate factor V by cleavage shift the balance toward excessive thrombus formation.

FIBRINOLYTIC SYSTEM

When repair of injured tissues is complete, the fibrin clot is dissolved by the enzyme plasmin. The fibrinolytic system is composed of the zymogen plasminogen and its thrombin-activated counterpart plasmin; the plasminogen activators (PAs) urokinase type (u-PA) and tissue type (t-PA); and their inhibitors, plasminogen-activator inhibitors PAI-1 and PAI-2 and α_2-antiplasmin (Fig. 46-13). Plasmin cleaves fibrinogen as well as fibrin. Cleavage of the cross-linked fibrin clot produces fibrin degradation products. D-Dimer is fibrin degradation products produced from the cleavage of two cross-linked fibrin monomers, releasing a fragment with two cross-linked D domains. Inhibition of the action of plasmin can occur by the activator inhibitors PAI-1 or PAI-2 or by inhibition of the enzyme itself with α_2-antiplasmin. u-PA is active in the extravascular compartment, whereas t-PA functions to activate plasminogen within the vasculature. Antithrombin also inhibits plasminogen activation. Defects in the fibrinolytic system have been associated with excessive thrombosis or bleeding. Recombinant t-PA is used to lyse pathologic thrombi.

PHYSIOLOGIC ALTERATIONS OF COAGULATION AND FIBRINOLYSIS IN THE NEONATE

Many differences in the neonatal coagulation system have been described. Understanding of the newborn hemostatic system has been hampered by difficulties in obtaining adequate control groups of healthy newborns and because the values of many coagulation factors change rapidly as gestational age and postnatal age progress. Coagulation and fibrinolytic factors do not cross the placenta and are reported to begin to appear in the fetal circulation by 10 weeks' gestational age. Normal ranges for most components of the coagulation, anticoagulation, and fibrinolytic systems are available for full-term infants and for infants born as prematurely as 30 weeks' gestation (Tables 46-16 to 46-18) (see "Laboratory Testing of the Neonatal Hemostatic System," below). The proposed etiologies for the differences in the newborn hemostatic system relative to the adult system include decreased synthesis of factors in the immature liver; decreased posttranslational modification of some factors to active forms due to low vitamin K levels; enhanced clearance; general activation of the coagulation system at birth, with resultant consumption of factors; and synthesis of less-active fetal

Figure 46–13. Plasminogen activation cascade. The proenzyme plasminogen is activated to the enzyme plasmin by tissue-type plasminogen activator (t-PA) or urinary-type plasminogen activator (u-PA). These two enzymes are inactivated after reaction with plasminogen activator inhibitor-1 (PAI-1) or plasminogen activator inhibitor-2 (PAI-2). Plasmin is capable of degrading fibrin clots to low-molecular-weight fibrin degradation products. Plasmin may be inactivated by α_2-antiplasmin.

All factors except fibrinogen and plasminogen are expressed as units per milliliter where pooled plasma contains 1 U/mL.

Plasminogen units are those recommended by the American Society of Hematology Committee on Thrombolytic Agents (CTA). All values are expressed as mean ± 1 SD.

aPTT, activated partial thromboplastin time; HMWK, high-molecular-weight kininogen; PT, prothrombin time; TCT, thrombin clotting time; vWF, von Willebrand factor.

From Andrew M, et al: The development of the human coagulation system in the full-term infant, *Blood* 70:165, 1987.

forms of some proteins. Most factors have reached adult levels by 6 months of life if not sooner. Factors VIII, V, fibrinogen, and XIII levels are normal at birth. Protein C levels remain low until later in childhood.

Several differences in the fibrinolytic system exist in the newborn: plasminogen and α_2-antiplasmin levels are low, whereas t-PA and PAI levels are twice the normal level for adults. α_2-Macroglobulin, an inhibitor of many proteolytic enzymes, including thrombin and plasmin, has been reported in infants at levels 2½ times the normal values for adults. The cumulative result of these alterations is that plasmin activity is diminished in the newborn.

Defects in the Hemostatic System

In addition to physiologic changes, acquired and congenital defects in the hemostatic system can occur in the neonate, placing the infant at risk for bleeding or thrombosis. Evaluation of the hemostatic system must distinguish alterations that are considered physiologic for gestational and postnatal

HC II (U/mL)	0.89	(0.45-1.40)	0.96	(0.66-1.26)
Protein C (U/mL)	0.57	(0.31-0.83)	0.96	(0.64-1.28)
Protein S (U/mL)	0.82	(0.44-1.20)	0.92	(0.60-1.24)

All values are expressed in units per milliliter, where pooled plasma contains 1.0 U/mL. All values are given as a mean followed by lower and upper boundary encompassing 95% of the population. Between 0 and 75 samples were assayed for each value for the newborn.

AP, antiplasmin; AT, antithrombin; C_1-INH, C_1 esterase inhibitor; HC, heparin cofactor; M, macroglobulin.

From Andrew M, et al: Development of the human coagulation system in the healthy premature infant, *Blood* 72:1651, 1988.

age from those that are abnormal. Consideration is then given to the patient's clinical status.

Although acquired defects are much more common, an otherwise healthy infant with excessive bleeding or thrombosis is more likely to have a congenital defect than is a sick infant with similar symptoms. Many patients with congenital abnormalities of hemostasis have symptoms and signs in infancy, and some of the presentations are unique to the neonatal period. Excessive bleeding can appear as an expanding cephalohematoma, prolonged bleeding after circumcision, oozing from venipuncture and line placement sites, or bleeding from the umbilicus. The ill infant can bleed from the bladder, gastrointestinal tract, or mucous membranes. Joint bleeding is distinctly uncommon in early infancy. Intracranial hemorrhage, especially in an otherwise healthy term infant, is an unusual but important presentation of a hemostatic defect.

LABORATORY TESTING OF THE NEONATAL HEMOSTATIC SYSTEM

Laboratory evaluation of a bleeding infant is especially challenging because the patient's small blood volume, often coupled with the poor regenerative potential of an ill infant, limits the total volume of blood available for testing. Because heparin adheres tightly to the walls of the tubing connected to intravenous catheters, most measures of coagulation are reliably performed only on free-flowing blood specimens obtained from an atraumatic venipuncture. Some centers place blood-drawing intravenous lines that are flushed or maintained with saline. Although sometimes successful, small clots can form within the catheter or at the tip, resulting in consumption of clotting factors and falsely abnormal results on coagulation testing. Cord blood may be used for coagulation factor assays and other testing if the specimen is immediately obtained by venipuncture from a double-clamped segment of the cord. Fetal blood specimens can be obtained, by ultrasound guidance, in fetuses as young as 20 weeks' gestation (see Chapter 8).

The higher hematocrit and resultant smaller volume of plasma per milliliter of whole blood in the newborn can alter the plasma-to-anticoagulant ratio, resulting in over-anticoagulation and falsely prolonged endpoints in some coagulation assays. Special sample tubes should be prepared for coagulation testing in infants with a hematocrit above 55%, so that the amount of anticoagulant added maintains the correct anticoagulation. If a patient is very anemic, excessive plasma per milliliter of whole blood will be sampled, and the plasma will be inadequately anticoagulated if standard sample tubes are used. To avoid falsely low results in some coagulation tests, special sample tubes should be prepared for patients whose hematocrit is below 25%.

Normal ranges for most components of the coagulation, anticoagulation, and fibrinolytic systems are available for full-term infants and for infants born as prematurely as 30 weeks' gestation (see Tables 46-16 to 46-18). In 2006, Monagle's group reevaluated the validity of these reference ranges and showed that the normal ranges are somewhat dependent on reagents and instruments used for testing.[59] Validation of reference ranges in the local laboratory is essential. Factors I, V, VIII, XIII, and vWF approximate adult ranges in the term newborn. Because the physiologic concentrations of some coagulation and fibrinolytic proteins is quite low in the neonatal period, definitive diagnosis can require repeat testing at a time when the expected normal range for age of the factor in question can be distinguished from a deficiency state (Fig. 46-14). The aPTT commonly is used as a screening coagulation test in older infants, children, and adults, but because most of the factors tested are normally low in the newborn, results are difficult to interpret. Results of the PT assay are only slightly prolonged in infants of more than 32 weeks' gestation. A small volume, whole blood, point-of-care assay for the activated clotting time (ACT) is discussed later in the "Extracorporeal Membrane Oxygenation" section.

Measurement of the non–γ-carboxyl glutamated clotting proteins induced by vitamin K absence (PIVKA) (Table 46-19) can be helpful in distinguishing vitamin K deficiency from factor deficiency. Des-γ-carboxy prothrombin (PIVKA II) is ordered for this indication. If gastrointestinal bleeding in an infant must be distinguished from swallowed maternal blood, a gastric aspirate, vomitus, or fecal material with gross blood present may be tested by the Apt test. Addition of 1% sodium hydroxide to a solution containing fetal hemoglobin retains the pink color of the mix. Adult hemoglobin turns yellowish brown if subjected to similar treatment.

Historically, bleeding time tests were used as a gross measurement of the interaction of platelets with the vascular endothelium and vWF in older children and adults. Bleeding time normal ranges for infants up to about 6 months of age are shorter than for adults. This has been attributed to the elevated levels of vWF, as well as the increase of the more functional high-molecular-weight multimers found in the newborn. The higher hematocrit and relative macrocytosis of the neonatal RBCs also may contribute. Bleeding time testing of the newborn is complicated by a lack of standardization and difficulties in reproducibility and has been largely replaced by platelet function screening tests such as the PFA-100 (Dade-Behring, Deerfield, IL), which measure platelet-vWF-fibrinogen interactions. Closure times in neonates tend to be shorter or within the lower limit of normal for older children and adults, presumably due to the presence of higher-molecular-weight multimers of vWF in neonates.

In an acquired or congenital coagulation factor deficiency state, a 50:50 mixture of patient plasma with pooled human plasma should yield normal results in a PT or aPTT assay. If these results are abnormal, investigation for a specific or nonspecific inhibitor of coagulation should be done.

Figure 46–14. Diagnostic algorithm for a bleeding neonate. aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; F, factor; plts, platelets; HMWK, high-molecular-weight kallikrein; PT, prothrombin time; RX, treatment; vWD, von Willebrand disease.

TABLE 46–19 Laboratory Findings in Selected Coagulation Defects

Factor	Bleeding Time	PT	aPTT	Thrombin Time	Comments
I (Afibrinogenemia)	A	A	A	A	Low fibrinogen level
Dysfibrinogenemia	N	A	±A	A	Fibrinogen activity lower than antigen levels
Heparin therapy	±N	N	A	A	Check factor level; PT, aPTT normalize with 50:50 mix

CONGENITAL DEFECTS IN HEMOSTASIS

Hemophilia A and B (factors VIII and IX deficiency, respectively) and von Willebrand Disease account for 95% to 98% of congenital bleeding disorders. Factors VIII and IX deficiencies are X-linked in inheritance, whereas von Willebrand disease can be inherited in an autosomal dominant or recessive fashion. The other congenital defects are recessively inherited coagulation disorders. All bleeding disorder patients should be managed with the help of hematologists expert in their care. In addition, genetic counseling about recurrence risks, family testing, and prenatal diagnosis is essential. Most defects with no detectable factor present are caused by deletions of a large portion of a gene (null mutation). Missense mutations can result in mild to severe disease. Rarely, combined deficiencies are due to defective genes coding for intracellular transport or involved in vitamin K metabolism or vitamin K-dependent post-translational modification. A North American Registry for rare congenital bleeding disorders tracks patients with deficiencies or defects in factors I, II, V, VII, X, and XIII.[1]

Hemophilias

A bleeding male infant, especially if otherwise clinically well, whose screening platelet count, PT, thrombin time, and fibrinogen concentration are within the normal range for age, is statistically most likely to have hemophilia. Because of the X-linked inheritance of both hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency), usually only males are affected, and more than half have a family history of the disorder. Factor VIII deficiency is five times as common as factor IX deficiency.[52]

Bleeding is less common in the newborn period than in later months, but for those who do bleed in the neonatal period, iatrogenic causes are most likely (circumcision, venipuncture, heel sticks). Less commonly, umbilical bleeding or intracranial hemorrhage may occur. Intracranial hemorrhage is often subdural rather than intraventricular. The incidence of intracranial hemorrhage in newborns with hemophilia has been estimated at about 3%. Hemorrhage into joints and deep muscle bleeding are the hallmarks of hemophilia. The clinical severity of the disease correlates with the patient's baseline factor level. Hemophilia is classified into three categories, based on the assumption that on average, a normal plasma factor activity level is 100%, and 1 mL of normal plasma has 1 unit of factor activity. Patients with severe, moderate, and mild disease have factor levels below 1%, between 1% and 5%, and above 5%, respectively. Patients with severe hemophilia bleed with little, or seemingly no, provocation (i.e., spontaneous hemorrhage). Both hemophilia A and hemophilia B are characterized by prolonged aPTT results with a normal PT test. Unfortunately, the physiologic prolongation of the neonatal aPTT makes diagnosis more difficult. Because factor VIII levels in the neonatal period approach adult levels, hemophilia A is reliably diagnosed, especially in those who are moderately or severely affected. An infant with evidence of factor VIII deficiency must at some point be evaluated for von Willebrand disease because this protein serves as the carrier for factor VIII, and an abnormality in the carrier protein can result in a low plasma factor VIII level. Because vWF levels are higher in the perinatal period, only severely affected patients (type 3 and some type 2 disease) might be expected to show bleeding problems. Factor IX levels are low at birth and do not reach adult values until 2 to 6 months postnatally. Severe factor IX deficiency can be diagnosed at birth, but mild and moderate hemophilia B often require subsequent confirmatory testing as the infant ages.

Therapeutic options include purified factor preparations and recombinant factors VIII or IX. Desmopressin (DDAVP) has been used for mild hemophilia A and for von Willebrand disease type 1 and some type 2 patients to increase release of factor VIII and vWF from endothelial stores. The antifibrinolytic agents ϵ-aminocaproic acid (Amicar) and tranexamic acid can be used in mucocutaneous bleeding to stabilize the fibrin clot and retard fibrinolysis. These agents are contraindicated in bladder or ureteral bleeding because of concerns about obstruction of urine flow by thrombi. Recombinant factor VIIa and prothrombin complex concentrates have been used in patients with coagulation factor inhibitors. Patients with hemophilia require specialty care by physicians expert in the disease management.

Von Willebrand Disease

Because vWF levels are higher at birth, and because there is an abundance of the most functional, highest-molecular-weight multimers during this period, the incidence of bleeding from von Willebrand disease in newborns is very low. Diagnosis usually requires repeat testing later in infancy. Because vWF serves as a carrier for factor VIII, those who are symptomatic in early infancy often have signs and symptoms associated with low factor VIII levels. The disorder can be classified into three types and many subtypes, and inheritance can be autosomal dominant or recessive. Type 1 disease is caused by a quantitative defect in vWF. vWF levels vary with blood type, with the lowest levels seen in patients with type O blood. Hematologists debate on whether type 1 should be called a disease because many affected patients and family members are not symptomatic. Those affected have mucosal type bleeding. Type 2 includes a large number of subtypes, all of which result from qualitative defects in vWF. These patients are more likely to have significant mucocutaneous bleeding symptoms. Patients with type 3 disease are either homozygotes or compound heterozygotes for qualitative and quantitative defects. These patients have a clinical presentation that is similar to hemophilia, including joint bleeding and intracranial hemorrhage. Laboratory tests include aPTT, platelet function screen, blood type, factor VIII coagulant activity, vWF antigen, vWF (ristocetin cofactor) activity, and multimeric analysis. Treatment is not needed for all patients. Mild cases (type 1 and some type 2 patients) can be managed with DDAVP and Amicar or tranexamic acid. Moderate or severe bleeding requires supplementation with one of the two currently available recombinant factor VIII concentrates that are copurified with vWF.

Factor XI Deficiency

Factor XI deficiency (hemophilia C) is inherited in an autosomal recessive manner and is not usually diagnosed in the neonatal period. It is most commonly reported in Ashkenazi Jews. Some patients may be diagnosed because an aPTT is prolonged. Unlike hemophilia A or hemophilia B, there is incomplete correlation between the degree of factor deficiency and hemorrhagic symptoms; some patients with very low levels have no bleeding history. Excessive bleeding typically occurs in the post-traumatic or postoperative setting. Certain anatomic locations, such as the genitourinary tract, are associated with an increased incidence of bleeding. These areas might have a high fibrinolytic rate that, according to the revised hypothesis of coagulation, would demand additional generation of factor Xa through the action of factor XIa. Bleeding after circumcision has been reported. Because factor XI levels normally are low in the neonatal period, the diagnosis must be confirmed by repeat levels in the older infant. Treatment involves fresh-frozen plasma (FFP). Factor XI deficiency has been described as a common finding in Noonan syndrome.

Other Congenital Factor Deficiencies

FACTOR XIII DEFICIENCY

More than 80% of patients with homozygous factor XIII deficiency have delayed hemorrhage of the umbilical cord stump.[26] Up to one third of these infants have intracranial hemorrhage at some time. Later in life, patients experience delayed hemorrhages, wound dehiscence, hemarthroses, and repeated spontaneous abortions. Because of the autosomal recessive type of inheritance, the family history most commonly is unhelpful. Factor XIII activity is not measured by the PT, aPTT, or any other routine screening test. Laboratory testing is based on an abnormally low quantitative factor XIII level (more sensitive). The functional test looking at instability of a patient's blood clot in a 5M urea solution can be normal in some symptomatic patients.

FACTOR I DEFICIENCY AND DEFECTS

Deficiency of factor I (fibrinogen) can be characterized as afibrinogenemia, hypofibrinogenemia, or dysfibrinogenemia. Deficiencies and dysfunction can be associated with bleeding as well as thrombotic episodes. Both the aPTT and the PT will be prolonged. Replacement is generally achieved by using cryoprecipitate, although low levels of fibrinogen are present in FFP as well.

FACTOR II DEFICIENCY OR FACTOR X DEFICIENCY

Life-threatening bleeding may present early on and can include intracranial hemorrhage, hemarthroses, umbilical cord bleeding, and hematomas. The aPTT and PT will be prolonged. Replacement at low levels is done with FFP, but in general, higher levels are needed for management of bleeding. Prothrombin complex concentrates are used for higher replacement levels.

FACTOR V DEFICIENCY

Patients experience mucocutaneous bleeding and bleeding after trauma or surgery. The PT and aPTT are prolonged. Treatment is with FFP.

COMBINED DEFICIENCY OF FACTORS V AND VIII

Most commonly, a defect in the gene coding for a lectin mannose-binding protein (*LMAN1*) affects the intracellular transport of these factors to the surface of the platelet after activation. Another gene, *MCFD2*, which is a cofactor of *LMAN1*, is defective in a minority of patients. These patients have hemarthroses, mucocutaneous bleeding, and posttraumatic bleeding. The PT and aPTT are affected. Replacement with FFP is usual for bleeding patients. DDAVP can be used to raise the factor VIII level.[54]

FACTOR VII DEFICIENCY

As with factor XI deficiency, there is poor correlation between activity level and clinical course in patients with factor VII deficiency. Some infants present with intracranial hemorrhage, whereas others with undetectable levels are asymptomatic. Mucocutaneous and deep tissue and joint bleeding can also be seen. Increased risk for thrombosis has been reported. The PT will be prolonged, whereas the aPTT should be normal for age. Treatment with a recombinant VIIa product is approved by the U.S. Food and Drug Administration for deficiency.

CONGENITAL MULTIPLE VITAMIN K-DEPENDENT FACTOR DEFICIENCY

This rare disorder is due to a defect in vitamin K epoxide reductase or in the γ-glutamyl carboxylase gene that adds glutamic acid as a post-translational modification to factors II, VII, IX, X, and proteins C and S. Umbilical cord bleeding, intracranial hemorrhage, mucocutaneous hemorrhage, and deep tissue bleeding can present early or later in life. Both the PT and aPTT will be prolonged.[10] Des-γ-carboxy prothrombin level will be normal, whereas prothrombin activity will be low. Treatment is with high-dose vitamin K and FFP.

ACQUIRED DEFECTS IN HEMOSTASIS

Hemorrhagic Disease of the Newborn

In 1894, Townsend described a series of 50 infants with self-limited bleeding that occurred mostly between the first and fifth day of life and that differed from classic hemophilia. Later investigators proposed decreased prothrombin levels as the cause of the bleeding tendency, and early feeding of infants with establishment of intestinal flora was shown to reduce the incidence of hemorrhage. Hemorrhagic disease of the newborn was formally defined and associated with a deficiency of vitamin K by the American Academy of Pediatrics Committee on Nutrition in 1961.

Vitamin K is a fat-soluble vitamin that is required for modifying coagulation proteins II (prothrombin), VII, IX, and X and anticoagulant proteins C and S. The post-translational γ-carboxylation of amino-terminal glutamic acid residues allows these factors to form complexes with other hemostatic proteins, through calcium, on a phospholipid surface. Localization of enzymes with their substrates and cofactors promotes very efficient reactions, and for the coagulation proteins, localization results in rapid, localized blood clot formation. Three forms of vitamin K have been identified: vitamin K_1 (phytonadione), which is present in green, leafy vegetables; vitamin K_2, which is synthesized by gastrointestinal flora; and vitamin K_3 (menadione), a synthetic, water-soluble form seldom used in neonates because of its association with hemolytic anemia. Placental transfer of the vitamin is poor, and vitamin K levels are low in newborn plasma and liver. Breast milk is a poor source of vitamin K relative to cow's milk or infant formulas supplemented with vitamin K. The gastrointestinal tract is sterile at birth, and its population with vitamin K-producing flora occurs after feedings are instituted. Because lactation requires several days to become established, infants who are exclusively breast-fed and those who are not fed orally are at risk for vitamin K deficiency. Broad-spectrum antibiotic therapy can be associated with vitamin K deficiency if the intestinal flora are eliminated. Because factors II, VII, IX, and X and proteins C and S are already low at birth, and deficiency of vitamin K results in production of dysfunctional coagulation proteins, infants with vitamin K deficiency are at risk for serious bleeding problems. Although proteins C and S are involved with control of coagulation, the clinical presentation of vitamin K deficiency is that of bleeding and not thrombosis.

Hemolytic disease of the newborn can be temporally divided into three types. Early disease occurs in the first 24 hours of life and generally is seen in infants born to mothers taking oral anticoagulant or anticonvulsant drugs. These infants often have serious bleeding, including intracranial hemorrhage. Classic disease occurs from days 1 to 7 and usually is characterized by cutaneous, gastrointestinal, or circumcision bleeding in infants who did not receive vitamin K prophylaxis at birth. Late-onset disease occurs in infants beyond 1 week of age and sometimes is associated with exclusively breast-fed infants. It is more commonly associated with chronic diseases that impair absorption of the fat-soluble vitamins or that obliterate intestinal flora, such as α_1-antitrypsin deficiency, abetalipoproteinemia, biliary atresia, hepatitis, cystic fibrosis, celiac disease, chronic diarrhea, and antibiotic therapy. Affected infants may develop cutaneous, gastrointestinal, or intracranial hemorrhages (30% to 60%).

An infant with hemorrhagic tendencies and a prolonged PT, with normal fibrinogen level and platelet count, from a statistical consideration almost certainly has HDN. Administration of vitamin K should be followed by cessation of bleeding symptoms and improvement of the PT within 24 hours. Specific factor assays, assays for the decarboxylated forms of the vitamin K-dependent coagulation proteins produced in the absence of vitamin K (PIVKA) or the des-γ-carboxyl prothrombin (PIVKA II), and direct measurement of the vitamin K level are usually not necessary.

The American Academy of Pediatrics recommends that all newborns receive prophylaxis with vitamin K_1. This usually is given as 0.5 to 1 mg of intramuscular vitamin K_1, but if injections are contraindicated, 2 mg of oral vitamin K_1 may be substituted with the first feeding, and repeated at weeks 1, 4, and 8. There were initial concerns about absorption of the oral form of the vitamin and about ensuring that the entire dose delivered is received. Oral administration is equally effective in preventing classic disease, but intramuscular administration is more protective against late-onset disease.[4] Infants who are treated with total parenteral nutrition or prolonged antibiotic therapy and those with acute or chronic malabsorption should be treated with vitamin K routinely. Identification of early warning signs and prompt treatment of HDN will decrease the incidence of serious bleeding, particularly intracranial hemorrhage. Serious bleeding may be treated with 10 to 20 mL/kg of FFP. In the setting of life-threatening hemorrhage, a prothrombin complex concentrate, or recombinant factor VIIa may be used.

Hepatic Disease

Many coagulation factors are synthesized in the liver, including factor V and the vitamin K-dependent factors II, VII, IX, and X. Hepatic damage can result in lower levels of these proteins. Because of its physiologic level of about 60% in newborns and because of its short half-life, the factor VII level often is used as an indicator of hepatic dysfunction. Measurement of factor V, a non–vitamin K-dependent, hepatically synthesized clotting factor that has a short half-life and that is present in similar amounts in the newborn and adult, can distinguish vitamin K deficiency from hepatic dysfunction.

Because vitamin K is metabolized back to its active form by liver microsomes, liver disease also can herald the rise of incompletely γ-carboxylated glutamic acid residues of the vitamin K-dependent factors. Cholestasis can interfere with vitamin K absorption, resulting in lower levels of active vitamin K-dependent factors. Factor VIII levels are elevated in hepatitis, whereas in DIC, general consumption of factors would be expected. Factor VIII and vWF levels are usually elevated in chronic liver disease. Altered hepatic clearance of fibrin degradation products can cause an elevation of these in plasma. Hypofibrinogenemia can occur in chronic liver disease with cirrhosis, although the more common laboratory findings are normal fibrinogen concentration with abnormal sialic acid residues on the molecules and resultant dysfibrinogenemia. If ascites develops, a general coagulopathy due to loss of clotting factors occurs. Finally, hepatic dysfunction may be associated with development of DIC, making interpretation of laboratory test results difficult. Coagulopathy can be managed with vitamin K supplementation, FFP, and cryoprecipitate. There are reports of the use of recombinant factor VIIa in pediatric patients with hepatic dysfunction.

Disseminated Intravascular Coagulation

DIC occurs as a result of activation and dysregulation of the hemostatic system and is characterized by generation of activated platelets and coagulation proteases, fibrin clot formation, and accelerated fibrinolysis. Depending on the patient's compensatory capacity to inactivate and clear the products of hemostasis and fibrinolysis and to regenerate components of the hemostatic system, the patient could experience bleeding or thrombosis, or both, or might only show laboratory evidence of DIC.

DIC in the neonate is most commonly due to infection, hypoxia, or tissue damage and necrosis. Neonatal viral infections, including rubella virus, herpesvirus, cytomegalovirus, and enterovirus; toxoplasmosis; systemic candidiasis; and bacterial infections, especially with gram-negative organisms, are common causes. Vascular malformations may be associated with DIC. The Kasabach-Merritt syndrome of kaposiform hemangioendothelioma with thrombocytopenia and hypofibrinogenemia is associated with DIC and often includes a microangiopathic hemolytic anemia.[36] The lesion might not be obvious, and identification could require radiographic imaging of the most common locations (i.e., brain, liver, spleen, and gastrointestinal tract). The placenta might have chorioangiomatous malformations associated with development of DIC, which is terminated by delivery of the infant and clamping of the umbilical cord. Finally, massive hemolysis, such as is sometimes seen in Rh incompatibility, can trigger DIC.

Diagnosis of DIC depends on clinical findings and laboratory tests. Typical laboratory results include thrombocytopenia; microangiopathic hemolytic anemia; prolongation of the PT; low levels of factors I (fibrinogen), V, and VIII, as well as AT III, protein C, and heparin cofactor II; elevation of fibrin and fibrinogen split products; and general depletion of coagulation factors. The D-dimer test signals degradation of cross-linked fibrin. This test commonly is positive in premature infants without DIC. The diagnosis of DIC relies on clinical information supplemented by confirmatory laboratory testing.

The most important therapeutic intervention is to treat the underlying cause of the DIC. Infants with bleeding or thrombosis also should be treated to control their hemostatic problem. Infants without clinical evidence of DIC might not require therapy. Treatment options include FFP and cryoprecipitate for factor replacement, exchange transfusion to remove fibrin and fibrinogen split products, and platelet transfusion. Anticoagulant therapy is not generally used because the benefit has not proved to outweigh the added risk for hemorrhage. Many institutions use transfusions to maintain the platelet count above 50×10^9/L, the fibrinogen above 100 mg/dL, and the PT within the normal range for age.

Respiratory Distress Syndrome

Respiratory distress syndrome is associated with increased pulmonary surface tension due to surfactant deficiency (see Chapter 44). At autopsy, some preterm infants with respiratory distress syndrome have fibrin deposition not only in the lungs but also in the liver, kidneys, and other organs. Because of the abnormal systemic fibrin deposition, various coagulation and fibrinolytic parameters have been evaluated in these infants, and antithrombotic or thrombolytic therapies proposed without clear benefit.

Extracorporeal Membrane Oxygenation

See Chapter 44.

Extracorporeal membrane oxygenation (ECMO) has been used in the treatment of many life-threatening, potentially reversible disorders. Intracranial hemorrhage, other hemorrhagic complications, infection, and thrombosis are significant complications of ECMO. Severe thrombocytopenia and low birthweight are associated with increased risk of hemorrhage. Probable causes of intracranial hemorrhage include thrombocytopenia, alterations in vascular flow, and heparin therapy.

Systemic anticoagulation with heparin traditionally continues for the duration of ECMO support to minimize the potential for clotting within the circuit and subsequent embolization. Because heparin is associated with bleeding complications and because the patient response to dosage is variable, close monitoring is essential. Traditionally, heparin therapy in ECMO patients has been monitored by the ACT, a rapid, whole blood, point-of-care test that requires a small volume sample. Patients are usually maintained close to a target time of 200 seconds; adjustments to the heparin drip depend on the ACT results as well as clinical perceptions of excessive hemorrhagic or thrombotic events in the patient or artificial circuit. Testing is performed every 30 to 60 minutes. PT, fibrinogen, platelet count, and hemoglobin are also monitored. Patients receive FFP, cryoprecipitate, platelets, and packed RBC transfusions to keep these values within target ranges identified by institutional protocols.

Current areas of investigation include using the direct thrombin inhibitor bivalirudin in place of heparin because of the likelihood of less bleeding and thrombosis as well as more predictable pharmacokinetics. Performing brief periods of ECMO without systemic anticoagulation is also being tested.

Thrombotic Disorders

STROKE

Stroke is defined as an acute neurologic syndrome caused by injury of the cerebral vasculature. Perinatal stroke occurs in the time period between 20 weeks of gestation and 28 days of postnatal life. Strokes can be due to arterial occlusion (acute ischemic stroke or AIS), cerebral venous thrombosis (CVT), or intracerebral hemorrhage (ICH). Although rare throughout childhood, AIS is relatively common in the neonatal period. Infants present with seizures, sensorimotor deficits, irritability, lethargy, or jitteriness. AIS of the neonate is an important cause of chronic neurologic disability.[19]

The diagnosis of AIS could be delayed until later in infancy when focal neurologic deficits become apparent. Thromboembolism from the fetal-placental circulation is believed to be the most common etiology, followed by poor or absent arterial blood flow or venous outflow obstruction. Congenital heart disease, anatomic defects, infection, perinatal asphyxia, and, arguably, thrombophilia track with AIS. Diagnostic imaging with magnetic resonance imaging, particularly if augmented with magnetic resonance angiography, diffusion weighted images, or magnetic resonance venography, is more sensitive than computed tomography (CT) scan. Management of neonatal stroke is supportive with seizure control, correction of metabolic abnormalities, adequate oxygenation and ventilation, and antibiotic therapy if appropriate. Cardioembolic stroke is treated with anticoagulation unless the size of the stroke is large or there is a hemorrhagic component, so that the risk for bleeding precludes anticoagulation. Aspirin or anticoagulation may be indicated in patients at risk for recurrent stroke. In general, risk for recurrence of AIS is low and is most likely in patients with underlying anatomic abnormalities and thrombophilia. Long-term outcomes in neonates tend to be superior to those of older children and adults, presumably because of the adaptive capabilities of the immature brain. CVT and sinovenous thrombosis (SVT) may cause venous obstruction to blood flow and resultant hemorrhagic or AIS. Trauma to cerebral sinuses or impaired blood flow during delivery may result in SVT. It is associated with perinatal complications, dehydration, trauma, or anatomic abnormalities of the head and neck, ECMO, and possibly with thrombophilia. Nonhemorrhagic lesions are often treated with anticoagulation.[31,64,68]

NEONATAL THROMBOSIS

Thrombotic complications occur more often in neonates than in any other age group in pediatrics. There is an unusually high predilection for thrombosis of major vessels, especially the inferior vena cava, renal vein and artery, aorta, portal vein, femoral arteries, and cerebral arteries and veins. Most are associated with catheter placement. Renal vein thrombosis is the most common type of thrombosis not related to presence of an indwelling catheter. The predisposing factors for thrombosis include vascular injury, alteration in the dynamics of blood flow, activation of the vascular endothelium, and the physiologic alterations of neonatal hemostasis. In the neonatal period, vessel wall damage from the catheter or from substances infused through it can promote thrombus formation. Hyperviscosity and turbulent blood flow from congenital heart disease or catheter placement can also contribute. In contrast to adult patients, it is estimated that more than 95% of the children who present with venous thrombosis have a serious underlying disease or condition. The most frequently associated diagnoses are congenital heart disease, cancer, trauma, major surgery, and systemic lupus erythematosus.

Dehydration, polycythemia, hypoxia, impaired perfusion, maternal diabetes, intrauterine growth restriction, and congenital deficiency of anticoagulant proteins are associated with increased risk for clot formation.

Despite the common practice of infusing heparin-containing solutions into indwelling catheters, the incidence of line-associated clots is high. Presenting signs and symptoms include loss of catheter patency, thrombocytopenia, and swelling of the area of the body associated with the blood vessel. Chylothorax can be seen with severe superior vena cava thrombosis. Asymptomatic catheter-related thrombi might occur in 10% to 90% of patients, depending on the method used to diagnose the thrombi. The true incidence of catheter-related venous thrombosis is unknown because the published studies are small and generally use suboptimal imaging techniques. Clots in the upper venous system are notoriously difficult to image, yet increasing numbers of infants and children are using venous catheters in the upper system. Immediate sequelae of thrombi can include pain, renal hypertension, organ failure, intestinal necrosis, and gangrene. Portal vein thrombosis secondary to umbilical venous catheter placement, particularly in a site with low venous flow such as intrahepatic, can manifest with signs and symptoms of an acute abdomen. More commonly, portal vein thrombosis remains silent until symptoms of chronic obstruction (splenomegaly, gastrointestinal bleeding) occur. Any clot can break off, or embolize, to the lungs. Pulmonary embolism is associated with significant morbidity and mortality. Right atrial thrombi can be seen in association with central venous catheters. In addition to catheter dysfunction, presenting symptoms can include cardiac murmur, heart failure, or persistent bacteremia. Arterial thromboses are most often associated with arterial catheter placement. Impaired blood flow beyond the clot can present as pain, poor perfusion, or organ dysfunction.

Renal vein thrombosis (RVT) accounts for up to 10% of venous thrombosis in infants and newborns and occurs primarily at this age. The most common cause of non–catheter-associated thrombosis in this age group, it occurs in association with dehydration, acidosis, sepsis, hypoxia or asphyxia, polycythemia, and maternal diabetes. Presenting signs and symptoms include flank mass, hematuria, proteinuria, and thrombocytopenia. Unilateral and left-sided renal vein thrombosis are the most common. Findings on ultrasound include enlargement of the involved kidneys, thrombus, and altered intrarenal and renal vein blood flow. Hypertension and renal damage are the most common serious sequelae.

Infants with congenital heart disease are at increased risk for venous thrombosis, pulmonary embolus, right atrial thrombus, and stroke. Appropriate prophylactic anticoagulation and treatment of thromboembolic disease reduces morbidity and mortality.[58]

Congenital and Acquired Laboratory Risk Factors for Thrombosis

The episodic nature of thrombosis indicates that acquired or environmental risk factors combine with genetic defects. It is estimated that 70% of families with thrombophilia have at least one identifiable genetic risk factor, yet within these kindreds, there are asymptomatic members who carry the identical genetic defects (Table 46-20). Some single point mutations (e.g., factor V Leiden and prothrombin 20210A allele; see later) are common in the general population. Laboratory tests for risk factors for thrombosis can be divided into two categories: genetic factors and abnormal laboratory phenotypes. Genetic risk factors include all known mutations that, through a gain or loss of function, tip the balance toward thrombus formation. Such loss-of-function mutations include deficiencies of anticoagulants AT, protein C, and protein S. Proteins are either abnormal in function or are present at reduced levels. Gain-of-function mutations, such as factor V Leiden and the prothrombin 20210A allele, are common. Abnormal laboratory phenotypes that are associated with increased risk for thrombosis include activated protein C resistance, lupus anticoagulant, hyperhomocysteinemia, and elevated factor VIII levels. At present, all molecular risk factors for venous thromboembolism are found within the anticoagulant and procoagulant pathways. Within the fibrinolytic and antifibrinolytic pathways, both genetic defects (dysfibrinogenemia, hypoplasminogenemia, dysplasminogenemia) and abnormal phenotypes (high PAI-1 levels, low t-PA levels) have been reported. There is very limited information about most molecular risk factors and the incidence of thrombosis in the neonatal period.

The anticoagulant proteins, protein C, protein S, and AT, are all inherited in an autosomal dominant manner. The medical literature reports many studies associating heterozygous deficiency states with an increased incidence of thrombosis, although these events are rare in the neonatal period. It is not entirely clear whether heterozygous deficiency of one of the coagulation inhibitors is sufficient to increase the risk for thrombosis because not all who are heterozygous for deficiency of one of these anticoagulant proteins have excessive thrombosis (see Table 46-20). Heterozygotes are not treated unless they have had an episode of thrombosis. Older children and adults who are considered to be in a period of high risk for thrombosis, such as during and immediately after surgery or childbirth, may receive prophylactic anticoagulation.

Homozygous protein C or protein S deficiency causes serious thrombotic events in the postnatal period. In the first few hours or days of life, affected patients manifest purpura fulminans, severe DIC, and life-threatening thromboses. Diagnosis is aided by laboratory tests, which yield results consistent with DIC and show no measurable protein by functional or immunologic assay. If instituted early in the course of the purpura fulminans, treatment can dramatically alter the clinical outcome. Initial therapy for protein C or S deficiency usually involves FFP. A protein C concentrate is available on a compassionate-use basis in the United States. Primary therapy should not be discontinued until the patient is placed on lifelong warfarin and has a therapeutic international normalized ratio of 3.0 to 4.0. Liver transplantation has also been attempted.

FACTOR V LEIDEN

Families with venous thromboembolism whose plasma was poorly responsive to the addition of activated protein C in an aPTT assay have been described. Eventually, the defect was traced to mutations in coagulation factor V that render it resistant to cleavage by activated protein C, and resistance to activated protein C is now the most common laboratory abnormality identified in patients with excessive venous thrombosis. These defects are inherited in an autosomal dominant fashion, and the homozygous state has been identified with an even higher thrombosis risk. Interactions with protein C, protein S, and prothrombin 20210A alleles causing enhanced risk for thrombosis have been reported.

PROTHROMBIN 20210A ALLELE

A mutation in the 3′-untranslated region of the prothrombin gene at nucleotide 20210 is associated with elevated prothrombin levels. Prothrombin levels greater than 115% of normal values are linked to a 2.1-fold increased risk for thrombosis. The molecular basis of the enhanced risk is not known.[67] Heterozygous carriers have a 2.8-fold increased risk for venous clot. The mutation interacts with factor V Leiden and protein S deficiency.

ELEVATED FACTOR VIII LEVELS

In the Leiden thrombophilia study, blood group (non-O), elevated vWF (>150%), and high factor VIII levels (>150%) were all associated with increased incidence of venous thrombosis.

TABLE 46–20 Molecular Defects and Risk for Venous Thrombosis in Adults

Deficient Protein	Increased Risk for Thrombosis	Incidence in Healthy Individuals (%)	Incidence in DVT Patients (%)	Incidence in Families with Thrombophilia (%)
AT III heterozygous	5×	0.05-1	1	4
Protein C heterozygous	7×	0.3	3	6
Protein S heterozygous	6-10×	?	1-2	6
Factor V Leiden heterozygous	7×	2-16	18	40
Factor V Leiden homozygous	80×	—	—	—

AT III, antithrombin III; DVT, deep vein thrombosis.
From Bertina RM: Molecular risk factors for thrombosis, *Thromb Haemost* 82:601, 1999.

Factor VIII levels higher than 150% stood out as an independent risk factor.[45]

DYSFIBRINOGENEMIA

The dysfibrinogenemias can manifest with bleeding or venous or arterial thrombosis, or they can be clinically silent. This diverse and rare group of defects is inherited in an autosomal dominant manner. Laboratory testing includes functional and antigenic assays of fibrinogen, which should show higher antigenic than functional results. The PT and aPTT also are usually prolonged. Thrombin time is abnormally prolonged.

INHERITED ABNORMALITIES OF FIBRINOLYSIS

Cases of dysplasminogenemia and hypoplasminogenemia associated with excessive thrombosis have been reported rarely, although the same defects have been identified in other family members who did not experience thrombosis. Differences between immunochemical and functional levels of plasminogen, and its activators and inhibitors have been used to diagnose these rare abnormalities.

TREATMENT OF THROMBOSIS

Treatment of thromboses is controversial because of the absence of randomized, controlled clinical trials in the neonatal population. Therapeutic options include supportive care, nonspecific measures (e.g., warming the involved or contralateral limb), anticoagulants, fibrinolytic agents, and (rarely) surgical removal. Most infants with a catheter-related thrombus are clinically asymptomatic. In these cases, the thromboses are underdiagnosed, and those patients who are diagnosed are treated supportively, with good response. Line removal is recommended in all catheter-related clots if possible. Patients who develop limb or organ compromise secondary to thrombosis must be treated more aggressively.

Numerous attempts have been made to develop pharmacologic agents that successfully restore physiologic balance to the coagulation system and prevent excessive thrombosis. The goal of anticoagulation is to prevent clot extension while augmenting the naturally occurring anticoagulation processes, and without causing bleeding. Unfractionated heparin and low-molecular-weight heparin (LMWH) are the most commonly used anticoagulants in infants. Long-term oral anticoagulation with warfarin is rare in neonates and usually is used for patients with recurrent thrombosis, mechanical heart valves, or thrombosis with a significant, ongoing, predisposing factor (homozygous protein C, protein S, or AT deficiency). Baseline laboratory testing in thrombosis includes platelet count, Hb, aPTT, PT, and fibrinogen. The impact of D-dimers and factor VIII activity are unclear. Thrombophilia testing is also controversial but commonly includes risk factors discussed previously such as protein C, protein S, AT, factor V Leiden, and prothrombin gene mutation. General guidelines for management are to maintain platelet count above 50,000 and fibrinogen level above 1 g/L and to correct any severe bleeding tendencies. Baseline assessment should be done for intracranial hemorrhage with CT scan or, if not practical, at least ultrasound. In adults, there are relative contraindications for initiation of anticoagulation, which include recent surgery or active bleeding. In the absence of validated criteria for the newborn, the risks and benefits of treatment compared with supportive care are carefully weighed. Consultation with an experienced pediatric hematologist is recommended. Monagle and colleagues have authored the eighth edition of evidence-based guidelines for the management of neonatal and pediatric thrombosis. Recommendations for management of specific types of thromboses are given.[58]

Unfractionated Heparin

Unfractionated heparin is an indirect thrombin inhibitor that binds antithrombin through a unique pentasaccharide to enhance inhibition of thrombin and factor Xa primarily, as well as factors XIa and IXa. A ternary complex of unfractionated heparin with AT and thrombin facilitates thrombin inhibition and requires both the pentasaccharide and a critical length of the unfractionated heparin, which is not present in LMWH. Unfractionated heparin is inexpensive, widely available, and rapidly reversible. Unfortunately, it must be given as a continuous infusion. Unpredictable pharmacokinetics require frequent monitoring of aPTT or heparin levels. Heparin therapy in the neonate cannot be directly based on the adult experience. Heparin clearance in the newborn is accelerated because of the larger volume of distribution and enhanced hepatic metabolism. Lower AT levels may affect the response to heparin both in terms of aPTT prolongation and by suboptimal clinical response. AT supplementation with FFP is sometimes suggested. Adverse effects include bleeding, unintended heparin overdose, heparin-induced thrombocytopenia, and osteoporosis. If bleeding occurs, heparin should be stopped. Protamine sulfate will inactivate unfractionated heparin at a ratio of 1 mg per 100 units. The dose will depend on the amount of unfractionated heparin given as well as the half-life of heparin, which is estimated at 1 hour in the neonate. Box 46-8 provides suggested guidelines for initiation of heparin therapy.

Laboratory testing is most useful in ensuring that a newborn is not overly anticoagulated and placed at excessive risk for hemorrhage. Because of the lower AT levels, newborn plasma tested by the aPTT overestimates the amount of unfractionated heparin in the plasma, whereas plasma tested in assays based on AT inhibition of exogenous thrombin or factor Xa yields results that underestimate the amount of unfractionated heparin in the plasma. The whole blood clotting time or activated clotting time (ACT) is sometimes used to monitor heparin therapy because the results can be obtained quickly. The test evaluates the ability of whole blood to clot, and the result can be prolonged by any abnormality in the cellular or fluid phase of the hemostatic system.

Low-Molecular-Weight Heparin

Because of the difficulties in obtaining venous access for continuous infusion of unfractionated heparin and the need for frequent laboratory monitoring associated with unfractionated heparin therapy, LMWHs are widely used for treatment or prophylaxis of thrombosis in adults. Less is known about their use in children and infants, but they are often used. LMWHs contain the critical pentasaccharide to inhibit factor Xa through AT, but they cannot form the ternary complex with AT and thrombin. LMWH therapy results in selective inhibition of factor Xa and theoretically puts the patient less at risk for hemorrhage. LMWHs do not prolong the aPTT. The longer half-life allows for daily or twice-daily

BOX 46–8 Recommendations for Unfractionated Heparin Therapy in Neonates

Pretreatment laboratory testing: CBC with platelets, aPTT, PT, serum creatinine, ALT
Loading dose: 75 U/kg IV over 10 minutes
Maintenance dose: 28 U/kg/hr continuous infusion
Laboratory monitoring:
- aPTT 4 hr after heparin loading dose given (use table to adjust dosing), then daily, *or*
- Daily anti-Xa level, unfractionated heparin—target range 0.35-0.6 anti-Xa units, *or*
- Daily anti-factor IIa level—target range 0.2-0.4 U/mL
- Daily CBC with platelets

Unfractionated Heparin Dosing Adjustments Based on aPTT Results

aPTT (sec)	Bolus (U/kg)	Hold Infusion (min)	Percent Change In Infusion Rate	Repeat aPTT (hr)
<50	50	0	↑20	4
50-59	0	0	↑10	4
60-85	0	0	0	24
86-95	0	0	↓10	4
96-120	0	30	↓10	4
>120	0	60	↓15	4

Duration of therapy (see text):
- 10-14 days, *or*
- 5-7 days; add warfarin or LMWH day 1 or 2 (extensive clot or PE: start warfarin on day 5 and treat with heparin for 14 days)

Precautions:
- If platelet count drops <150,000/μL, consider heparin-induced thrombocytopenia
- Avoid IM injections and arterial punctures

Unfractionated Heparin Antidote: Protamine Sulfate 10 mg/ml at a Rate not to Exceed 5 mg/min, Maximum Dose 50 mg

Time Elapsed since Last Heparin Dose (min)	Protamine Sulfate Dose (mg/100 U Heparin Received)—Maximum 50 Mg	aPTT after Protamine (min)
<30	1	15
30-60	0.5-0.75	15
61-120	0.375-0.5	15
>120	0.25-0.375	15

ALT, alanine aminotransferase; aPTT, activated partial thromboplastin time; CBC, complete blood count; IM, intramuscular; IV, intravenous, LMWH, low-molecular-weight heparin; PE, pulmonary embolus; PT, prothrombin time.
Adapted from the Protocol for Heparin Therapy, Hospital for Sick Children, Toronto, Canada, 1995.

dosing subcutaneously in adults. More predictable pharmacokinetics allow less laboratory monitoring using the anti-Xa assay. This assay is less widely and rapidly available than the aPTT used to monitor unfractionated heparin therapy. Heparin-induced thrombocytopenia and osteoporosis risks are less.

BOX 46–9 Recommendations for Low-Molecular-Weight Heparin Therapy in Neonates

Pretreatment laboratory testing
- CBC with platelets, aPTT, PT with international normalized ratio
- ALT, AST, bilirubin total and direct, serum creatinine

Recommended therapeutic target range: 0.5-1.0 antifactor Xa U/mL
Therapeutic dosing
- Enoxaparin
  - <2 mo of age: 1.5 mg/kg SC q 12 hr
  - >2 mo of age: 1.0 mg/kg SC q 12 hr
- Reviparin
  - <2 mo of age: 150 U/kg SC q 12 hr
  - >2 mo of age: 100 U/kg SC q 12 hr

Anti-Xa U/mL	Percent of Prior Dose	Repeat Anti-Xa
<0.35	125	4 hr after next dose
0.35-0.49	110	4 hr after next dose
0.5-1.0	Same dose (100)	Next day
1.1-1.5	80	4 hr after dose
1.6-2.0	70	4 hr after dose
>2.0	Hold until anti-Xa <0.5 U/mL, then 40	4 hr after dose

Laboratory monitoring
- Draw anti-Xa level 4 hr after dose given
- When anti-Xa level is 0.5-1.0 U/mL, repeat next day, then 1 week later and monthly after

---

ALT, alanine aminotransferase; aPTT, activated partial thromboplastin time; AST, aspartate aminotransferase; CBC, complete blood count; SC, subcutaneous.
Adapted from Lilleyman J, et al, editors: *Thromboembolic complications in pediatric hematology,* 2nd ed, New York, 1999m Churchill Livingstone.

Clinical studies in adults have shown that LMWH is as effective as crude heparin in preventing thrombosis but is associated with equal or fewer bleeding complications. Although the studies in pediatric patients are small, safety and efficacy have been reported for enoxaparin and dalteparin.[50,57] Pediatric dosing is age dependent and weight dependent (Box 46-9). Infants younger than 2 months require higher doses than older children to maintain therapeutic anti-Xa levels of 0.5 to 1.0 international units/mL. If bleeding occurs, the LMWH should be stopped. Protamine sulfate, given within 4 hours of LMWH dose at a ratio of 1 mg per 100 units of LMWH, will partially reverse the LMWH effect.

Oral Anticoagulation with Warfarin (Coumadin)

Oral therapy with warfarin (Coumadin) in neonates is often complicated by hepatic dysfunction, drug interactions, diet fluctuations, vitamin K supplementation in infant formulas, and poor venous access for laboratory monitoring. It is difficult to achieve and sustain therapeutic levels of drug. Efficacy and safety are related to time in the therapeutic range. Warfarin therapy should be supervised by an experienced pediatric hematologist or cardiologist. The action of warfarin is based on interruption of the vitamin K–dependent γ-carboxylation of factors II, VII, IX, and X and proteins C and S. The PT or international normalized ratio is used to monitor adequacy of anticoagulation (Box 46-10).

New Anticoagulation Agents in Infants

There is limited information on the use of the indirect thrombin inhibitor fondaparinux in children. This synthetic pentasaccharide is given subcutaneously and has been used in the treatment of patients with heparin-induced thrombocytopenia.[55] The direct thrombin inhibitor bivalirudin is of interest because its efficacy does not depend on AT levels in plasma and because this small molecule can become incorporated into the fibrin clot to inhibit both bound and circulating thrombin. Early reports of rapid clot resolution with less bleeding are intriguing and may suggest an alternative to fibrinolytic therapy or for anticoagulation in heparin-induced thrombocytopenia. The drug is administered by continuous infusion and is monitored by the aPTT.[81] Bivalirudin has also been used in patients with heparin-induced thrombocytopenia as an alternative anticoagulant.

Fibrinolytic Therapy

The goal of thrombolytic therapy is to degrade fibrin and dissolve the fibrin clot. Recombinant t-PA is the most commonly used agent (Box 46-11). It facilitates conversion of plasminogen to plasmin, enhancing degradation of fibrin, fibrinogen, and coagulation factors V and VIII. Bleeding complications have been a major concern in thrombolytic therapy in neonates, in addition to embolization or rethrombosis. Attention in older patients has focused on localizing therapy so that plasminogen associated with the thrombus is preferentially activated and systemic bleeding complications are minimized, but directed fibrinolysis is generally impractical in the small blood vessels of the neonate. In vitro and in vivo studies of thrombolytic therapies in the newborn have demonstrated different responses compared with adults, probably because of the physiologic differences in the fibrinolytic system. The neonate is resistant to t-PA and may require higher doses than those used in adults. Supplementation with heparin and FFP is sometimes appropriate. Consultation with an experienced pediatric hematologist is strongly encouraged for treatment and monitoring recommendations.

BOX 46–10 Recommendations for Warfarin Therapy in Neonates

- Pretreatment laboratory testing
  - CBC with platelets, aPTT, PT with international normalized ratio (INR)
  - ALT, AST, bilirubin total and direct
- Recommended target ranges for INR
  - 2.0-3.0, usual range
  - 2.5-3.5, mechanical heart valves
- Loading period
  - Lasts 3-5 days, or until a stable, therapeutic drug level is achieved
  - Begins 1-2 days after initiation of heparin therapy (for extensive DVT or pulmonary embolus, begin at day 5 of heparin therapy)
  - Dose on day 1: 0.2 mg/kg PO single daily dose, maximum 10 mg
    - Fontan procedure patients: 0.1 mg/kg, maximum 5 mg
    - Reduce loading dose if hepatic or renal dysfunction present or baseline INR >1.2
    - Monitor closely if potential for drug interactions exists
    - Consider amount of vitamin K in diet and supplements

Warfarin Dose Adjustments During Loading Period*

INR	Percent of Loading Dose to Be Given
1.1-1.3	100
1.4-3.0	50
3.1-4.0	25
>4.0	Hold until INR <4.5, then restart at 50

*Daily PO dose based on INR results.
Discontinue heparin 5 days after initiation of warfarin and when INR >2.0 daily × 2.

Warfarin Dose Adjustments During Maintenance Period*

INR	Percent of Previous Dose to Be Given
1.1-1.4	120
1.5-1.9	110
2.0-3.0	100
3.1-4.0	90
4.1-4.5	80
>4.5	Hold until INR <4.5, then restart at 80

*Daily PO dose based on INR results.
Discontinue heparin 5 days after initiation of warfarin and when INR >2.0 daily × 2.

- Laboratory monitoring
  - Daily INR until therapeutic level reached on 2 consecutive days
  - INR weekly if stable; may require more frequent testing
- Warfarin antidote
  - No bleeding: vitamin K_1
    - Rapid reversal and anticipate warfarin treatment in future: 0.5-1 mg SC
    - Rapid reversal and no future need for warfarin: 2 mg SC
  - Clinically significant bleeding: 2-5 mg vitamin K_1 IV over 10-20 min and fresh-frozen plasma (20 U/kg) or factor IX concentrate containing other vitamin K–dependent factors (50 U/kg).

DVT, deep vein thrombosis; IV, intravenous; SC, subcutaneous.
Adapted from the Protocol for Coumadin Therapy, Hospital for Sick Children, Toronto, Canada, 1995.

BOX 46–11 Institutional Protocol* for t-PA Use in Blocked Catheters

Instill t-PA (2 mg/mL) into catheter; volume of t-PA should be based on catheter type.

- Infant Broviac: 0.5 mL
- Single-lumen Broviac: 1 mL
- Double-lumen Broviac: 1.5 mL each lumen
- Port-a-Cath: 2 mL

Allow the drug to dwell for 2 hours. At the end of 2 hours, the drug should be withdrawn.

This process may be repeated one additional time if needed.

---

*Protocol for St. Louis Children's Hospital, 2007.
t-PA, tissue plasminogen activator.

In the face of life- or limb-threatening thrombosis, thrombolytic therapy is considered. Dose, duration of thrombolysis, and concurrent or subsequent use of heparin are controversial (Table 46-21).[58]

Regulation of Platelet Production

Megakaryocytopoiesis is regulated in vivo mainly by thrombopoietin (TPO). In adults, the liver and, to a lesser extent, the kidney and bone marrow have been identified as sites of TPO production. Preterm infants have lower TPO levels than term infants, and TPO levels in infants are lower than those of adults, regardless of platelet count. Fetal and neonatal cells demonstrate a dose-response effect when exposed to TPO. The thrombocytopenia present in some neonates may be due to ineffective TPO production. In adults and children, serum TPO concentrations are inversely related to the mass of megakaryocytes and circulating platelets. The regulation of TPO levels appears to be mediated by the MPL receptor found on platelets and megakaryocytes, and on other hematopoietic progenitors in lesser concentrations. These cells bind, internalize, and degrade the constitutively produced growth factor. The therapeutic role of recombinant TPO in the neonatal period is not established.

The normal circulating platelet count for all ages ranges from 150,000 to 400,000/µL. Average platelet counts are slightly lower in preterm infants and increase with gestational age. Two thirds of total body platelets circulate; the other third are located within the spleen. The average platelet life span is 7 to 10 days, although survival of transfused platelets in a thrombocytopenic recipient is reduced proportionately to the severity of the thrombocytopenia.

Most patients with thrombocytopenia are asymptomatic. When it does occur, bleeding is usually mucocutaneous. Severe thrombocytopenia can manifest with petechiae. Larger purpuric lesions, ecchymoses, may appear at sites of injury. Epistaxis, hematuria, and prolonged bleeding at incision or venipuncture sites can occur.

Treatment decisions are difficult, because of the lack of direct correlation between platelet count and bleeding risk. The risk for hemorrhage is affected by other factors such as coexisting coagulation defects, trauma, surgery, and poorly understood patient characteristics. In older children and adults, serious spontaneous bleeding does not occur until the platelet count is less than 20,000/µL. Many physicians use 10,000 to 20,000/µL as the threshold for intervention. This is based on data from a study of children with leukemia in whom the risk for serious bleeding increased below this range. Because of the increased risk for intracranial hemorrhage in neonates, a threshold of 20,000 to 50,000/µL is often used for the first 96 hours of life, when the risk is highest (see Part 2 of this chapter). Consideration is given to the etiology of the thrombocytopenia. Patients with a production defect are more likely to have serious bleeding than those with a destructive platelet problem, because in the latter cases, the platelets tend to be larger and more functional. If bone marrow transplantation or frequent transfusions are anticipated, the transfusion threshold is generally lowered in an attempt to minimize the risk for alloimmunization or graft failure.

Platelet Function

Platelets adhere to subendothelial components at the site of endothelial injury through glycoprotein receptors GP Ib/IX/V, Ia/IIa, and IIb/IIIa. Receptor-ligand binding results in platelet activation with shape changes and degranulation from α-granules (vWF, platelet factor 4, thrombospondin, fibrinogen, fibronectin, factors V and VIII, platelet-derived growth factor) and dense granules (adenosine diphosphate, adenosine triphosphate, calcium, serotonin, epinephrine). Platelet aggregation is mediated through GP IIb/IIIa and fibrinogen to link platelets together. Platelets also host the formation of a fibrin clot on their phospholipid membrane surface in the presence of calcium and coagulation factors.

Quantitative defects of platelets, or thrombocytopenia, result in excessive bleeding and bruising when platelet counts drop below 100,000/µL. Spontaneous, serious hemorrhage from isolated thrombocytopenia is unusual when platelet counts are more than 20,000/µL. Thrombocytopenia can be accompanied by qualitative platelet disorders. Qualitative disorders in older children and adults are most commonly acquired and associated with drugs or uremia, but in the otherwise healthy newborn with mucocutaneous bleeding, consideration must be given to congenital defects in platelet function. Some of the defects are associated with decreased production or increased platelet clearance. A few are characterized by changes in platelet size or by associated defects in white blood cells. Congenital qualitative defects include abnormalities in glycoprotein receptors and defective or deficient granules or secretion of the granules.

Platelet counts are determined most commonly in an automated cell counter in the laboratory. Abnormally sized platelets require manual counting. Review of the peripheral blood smear for platelet morphology, color (rule out gray platelet syndrome), white blood cell inclusions, and evidence of schistocytes (DIC) is helpful. A common platelet function screening instrument, the PFA-100, can test the interaction of platelets with fibrinogen and vWF, assuming the platelet count is at least 100,000/µL. The gold standard test for platelet function, platelet aggregometry, is rarely done in the newborn period because it requires a large volume of blood. Testing for platelet glycoprotein receptor

TABLE 46–21 Thrombolytic Therapy

Anticoagulation	Loading Dose	Continuous Infusion	Pretreatment Duration	Monitoring Tests	Reversal Tests	Agents
Urokinase	4400 U/kg	4400 U/kg/h	Up to 48 h or until clot lysis	CBC, plts, PT, PTT, fibrinogen, FDP, cranial ultrasound	Fibrinogen, FDP, clot imaging[*,†]	Fresh-frozen plasma, cryoprecipitate
Recombinant t-PA	0.5 mg/kg	0.04-0.5 mg/kg/h	48-72 h or until clot lysis	CBC, plts, PT, PTT, fibrinogen, FDP, cranial ultrasound	Fibrinogen, FDP, clot imaging[‡]	Fresh-frozen plasma, cryoprecipitate
			If no response, consider concurrent plasminogen therapy

components and markers of activation by flow cytometry is available in specialized laboratories. Unfortunately, specialized platelet studies must be performed rapidly on fresh platelets and so generally require travel by the patient to the reference laboratory.

Thrombocytopenia

Etiologies for thrombocytopenia can be divided into decreased production or increased destruction. Often, both are present in the neonate. Infection, liver disease, and drug effects can be associated with decreased production and increased destruction of platelets. Congenital cytomegalovirus and rubella often are complicated by thrombocytopenia secondary to both underproduction and increased destruction. HIV infection also can be associated with thrombocytopenia (see Chapter 39). Certain trisomies are also associated with thrombocytopenia, including trisomy 13 and trisomy 18. DIC, necrotizing enterocolitis, hypoxia, immune destruction, maternal history of preeclampsia, and thrombosis are examples where increased consumption of platelets can reduce counts. Cardiopulmonary bypass and ECMO are associated with activation of platelets and the coagulation system as well as hemodilution. In hypersplenism, a larger proportion of platelets remain in the spleen, so peripheral counts can be lower. Heparin-induced thrombocytopenia, triggered by immune response to anticoagulation, is a rare cause of thrombocytopenia in the neonate. Renal failure is associated with qualitative defects in platelet function and variable thrombocytopenia. Congenital qualitative and quantitative defects are rare causes of decreased platelet production. Infiltration of the bone marrow by malignant cells (leukemia, neuroblastoma) or by histiocytes in hemophagocytic lymphohistiocytosis (see “Hemophagocytic Lymphohistiocytosis Syndrome,” later) is rare in the neonatal period.

Thrombocytopenia is rare in the healthy term infant (<1%) but commonly seen in the neonatal intensive care unit. One study estimated that 22% of the neonatal intensive care unit patients had low platelets.[18] Prematurity is one factor. In a retrospective study of 284 infants with extremely low birthweight, thrombocytopenia was reported in 73% of infants with birthweight of less than 1000 g. In infants weighing less than 800 g at birth, low platelets were seen in 85%. Counts were less than 50,000/µL and less than 100,000/µL for 28% and 56%, respectively.[20]

THROMBOCYTOPENIA RESULTING FROM INCREASED PLATELET DESTRUCTION

Neonatal Alloimmune Thrombocytopenia

See Chapter 18.

Neonatal alloimmune thrombocytopenia (NAIT) results from placental transfer of maternal alloantibodies directed against paternally inherited antigens that are present on the fetal platelets but absent from maternal platelets. In general, these are IgG antibodies, which recognize protein antigens rather than oligosaccharide determinants. This condition is analogous to Rh hemolytic disease of the newborn, but in contrast, NAIT can develop in the first pregnancy. The platelet antigens form early in gestation, and maternal antibody crosses the placenta and into the fetal circulation as early as midtrimester. Severe thrombocytopenia can result, with intracranial hemorrhage estimated to occur in 10% to 20% of affected infants. Many of the intracranial hemorrhages (25% to 50%) occur in utero.[12]

In white populations, the most frequently implicated alloantigen in NAIT is HPA-1a, which accounts for 78% of serologically confirmed cases. Incompatibility for the HPA-5b alloantigen is the next most common cause, followed by HPA-15b. About 98% of whites express the HPA-1a antigen on their platelets; most of the remaining 2% are homozygous for an alternative allele that encodes the HPA-1b antigen. The incidence of NAIT is about 1 in 2000 births, which is much lower than the predicted incidence based on the distribution of the HPA-1a and HPA-1b alleles in the population. Other immune response genes appear to regulate HPA-1a alloantibody formation. Women with the HLA-DR3 antigen have about a 20-fold relative risk for forming HPA-1a alloantibodies. In the Asian population, incompatibility of the HPA-4 (Pem) system is the most common cause of NAIT (80%), followed by HPA-3.[77]

NAIT should be suspected in an otherwise healthy infant with isolated thrombocytopenia at the time of birth. The degree of thrombocytopenia can be severe, with platelet counts often lower than 10,000/μL in the first day of life. The maternal platelet count is normal, an important laboratory value for distinguishing this condition from neonatal thrombocytopenia secondary to maternal idiopathic thrombocytopenic purpura (ITP) (discussed later). Mucocutaneous bleeding is common in patients with NAIT. These patients are at increased risk for intracranial hemorrhage, both prenatally and postnatally. The pronounced bleeding diathesis associated with anti-HPA-1a NAIT probably reflects the combination of severe thrombocytopenia and antibody-mediated interference with the function of the GP IIb-IIIa complex on the few remaining platelets.

The diagnosis of NAIT is confirmed by serologic testing of maternal serum for antiplatelet antibodies and immunophenotyping of maternal and paternal platelets. Genotyping of maternal and paternal blood to establish platelet antigen genotypes is preferable when available. Because delays may be associated with serologic and platelet antigen testing, therapy should be initiated as soon as the diagnosis is suspected. The treatment of choice for severe isoimmune thrombocytopenia is transfusion of washed irradiated maternal platelets. Term infants tend to receive platelet transfusion for bleeding and less than 30,000/μL, whereas preterm infants and ill infants may have a transfusion threshold of less than 50,000/μL. Suspected infants should have a head CT scan if possible, or alternatively, a cranial ultrasound to look for intracranial hemorrhage. Because the risk for intracranial hemorrhage drops after 3 to 4 days, the otherwise healthy term infant can be managed with lower platelet counts. When maternal platelets are not available, irradiated, random-donor platelet infusions can be used; however, a modest and short-lived increase in the platelet count might be observed. Intravenous γ-globulin (1 g/kg daily for 2 days) or corticosteroids (methylprednisolone, 2 mg/kg per day), or both, also can be used as temporary measures. Platelets produced by neonates with NAIT often exhibit accelerated clearance until antiplatelet antibody is removed from the circulation. Consequently, it is not unusual for additional transfusions of maternal platelets to be required after the first few weeks of life.

The likelihood is high that subsequent infants born to these mothers will be affected. Because the severity of intracranial hemorrhage tends to increase in later pregnancies, detailed counseling about the risk for recurrence should be provided to the family at the time that the first infant's thrombocytopenia is diagnosed. Although the thrombocytopenia may have resolved before completion of the full diagnostic laboratory evaluation, it is important that the diagnosis and presumed antigen incompatibility be confirmed by formal serologic and genotypic testing in order to guide the management of future pregnancies. Antibody titers begin to decline after delivery, so the evaluation should be initiated in the postpartum period. Because the likelihood of thrombocytopenia in subsequent infants depends on whether the father is HPA-1a homozygous or HPA-1a or HPA-1b heterozygous, it is desirable to perform DNA-based genotyping.

Neonatal Thrombocytopenia Resulting from Maternal Immune Thrombocytopenia

Neonatal thrombocytopenia can occur in infants of mothers with ITP, lupus erythematosus, or other autoimmune disorders (see Chapter 18).[79] This diagnosis should be considered when both the neonate and the mother have evidence of thrombocytopenia. The diagnosis should be suspected in infants of mothers with a previous history of ITP because neonatal thrombocytopenia has been observed in infants of mothers rendered asymptomatic of chronic ITP by splenectomy. Maternal ITP must be distinguished from the mild decrease in platelets that often accompanies pregnancy at term, presumably due to plasma volume expansion.

The thrombocytopenia associated with maternal ITP is generally milder than in NAIT, and bleeding is less common. A large study of these patients revealed that the incidence of cord platelet counts of less than 50,000/μL is only about 3%. Affected infants should undergo evaluation for intracranial hemorrhage by head CT or cranial ultrasound. The babies should be followed closely until counts are clearly rising because platelet counts often fall in the first few days after birth. As described in the discussion on NAIT, prophylactic platelet transfusion is considered, especially in the first 96 hours of life and in ill or premature infants. Intravenous γ-globulin (1 g/kg daily for 2 days) elevates the platelet count in most patients. Corticosteroids (methylprednisolone, 2 mg/kg per day) may be used in addition to or instead of intravenous γ-globulin therapy.

The perinatal management of mothers with immune thrombocytopenia is controversial. Because the cord platelet count rarely is less than 50,000/μL, perinatal intracranial hemorrhage is rare and not necessarily related to delivery. There are no reliable predictors of severe thrombocytopenia in the newborn except for direct determination of the fetal platelet count by percutaneous umbilical venous sampling, but this procedure is rarely justified in this condition. The degree of maternal thrombocytopenia is a poor predictor of the degree of neonatal thrombocytopenia. Measuring maternal platelet-associated IgG and maternal serum antiplatelet IgG has been proposed as a possible predictor, but has not proved generally useful.

Other Conditions Associated with Increased Platelet Destruction

Kasabach-Merritt syndrome associated with kaposiform hemangioendothelioma should be considered in cases of neonatal thrombocytopenia with DIC. Infection can trigger DIC, hepatosplenomegaly, and bone marrow suppression of platelet production. The relatively rare type 2b von Willebrand disease can manifest as isolated thrombocytopenia in the newborn period. Immune thrombocytopenia can accompany some cases of hemolytic disease of the newborn. For example, blood group O-B incompatibility can result in both hemolysis and thrombocytopenia because the B antigen is expressed on platelets. Maternal treatment with some drugs (penicillins, digoxin, and some anticonvulsants) may trigger an IgG response, which can cross into the fetal circulation and cause low platelets. Necrotizing enterocolitis is often associated with thrombocytopenia and bleeding. Thrombosis, particularly renal vein thrombosis, can be associated with consumption of platelets and low counts.

Another recently recognized cause of immune thrombocytopenia is autoimmune lymphoproliferative syndrome (ALPS).[70] This syndrome manifests early in childhood in persons who inherit mutations in genes critical for lymphocyte apoptosis. In autoimmune lymphoproliferative syndrome, defective lymphocyte apoptosis results in the survival of normally uncommon "double-negative" $CD3^+$, $CD4^-$, $CD8^-$ T cells and the development of autoimmune disease. Most cases of autoimmune lymphoproliferative syndrome involve mutations in the lymphocyte surface protein Fas or signaling molecules downstream of Fas. In addition to immune thrombocytopenia, children with ALPS can exhibit autoimmune hemolytic anemia, neutropenia, lymphadenopathy, and splenomegaly.

CONGENITAL THROMBOCYTOPENIA DUE TO UNDERPRODUCTION OF PLATELETS

Wiskott-Aldrich Syndrome

This X-linked syndrome is characterized by immunodeficiency, eczema, and thrombocytopenia secondary to decreased production.[60] Often only the thrombocytopenia is recognizable at birth. The platelets of patients with Wiskott-Aldrich syndrome are abnormally small (average diameter, 1.8 μm versus 2.2 μm). Cell-mediated immunity progressively declines with age. The number and phenotype of blood lymphocytes are normal. Serum immunoglobulins are abnormal: IgM is diminished, whereas IgA and IgE are elevated. The immune response to polysaccharide antigen is abnormal. The Wiskott-Aldrich gene *WAS* has been identified through positional cloning.[24] It encodes a cytoskeletal protein (WASP) that is expressed in hematopoietic progenitor cells. Symptomatic bleeding secondary to thrombocytopenia can be managed with irradiated single-donor platelet transfusions, although this rarely is necessary. The definitive treatment for Wiskott-Aldrich syndrome is allogeneic bone marrow transplantation.

Congenital Amegakaryocytic Thrombocytopenia

Amegakaryocytic thrombocytopenia is an autosomal recessive, rare cause of congenital thrombocytopenia. The degree of thrombocytopenia can be profound, with a count often less than 20,000/μL.[7] Bone marrow aspiration reveals a markedly reduced number of megakaryocytes, which may be dysplastic. Infants have severe mucocutaneous bleeding and can have intracranial hemorrhage in the perinatal period. As with other congenital bone marrow failure syndromes, this condition may evolve into progressive bone marrow failure or leukemia. Mutations in the *MPL* gene, which encodes the TPO receptor, are responsible for disease.[7]

Patients generally are dependent on platelet transfusions and have a short life span; the mean age of death is 5 years. Factors that contribute to this poor prognosis include the risk for hemorrhage, complications of chronic platelet transfusion (i.e., sensitization), and the risk for evolution into bone marrow failure or leukemia. In addition to transfusion support with single-donor, irradiated platelets, trials of growth factors (e.g., IL-11, TPO) have been attempted, with mixed success. Allogeneic bone marrow transplantation should be considered if a healthy HLA-matched sibling is available.

Thrombocytopenia with Absent Radii Syndrome

Thrombocytopenia with absent radii (TAR) syndrome is another rare autosomal recessive cause of severe neonatal thrombocytopenia. Patients with this condition have no radii but can have normal or hypoplastic thumbs (Fig. 46-15).[7] Other skeletal anomalies can accompany the absent radii, including ulnar shortening, thumb hypoplasia, and scapular changes. Platelet counts in neonates are usually less than 50,000/μL. Bone marrow aspiration reveals a decrease in megakaryocytes, although this test is not required to make the diagnosis. Patients have mucocutaneous bleeding, especially in the first year of life, when the thrombocytopenia is most pronounced. As infants, these patients often require transfusions of single-donor, irradiated platelets to maintain a platelet count greater than 10,000/μL. After the first year of life, platelet-transfusion dependence usually diminishes. This condition has a much better prognosis than amegakaryocytic thrombocytopenia; the survival curve for TAR plateaus above 70% by 4 years of age.

The molecular pathogenesis of TAR is unknown. Levels of TPO are elevated in patients with TAR, yet TAR platelets fail to respond to recombinant TPO. Defective signal transduction through the *MPL* pathway has been suggested.[7] Comparative genomic hybridization studies have identified a 200-kb deletion on chromosome 1q21.1 in 30 of 30 affected individuals and in 32% of unaffected family members, suggesting that microdeletion on 1q21.1 is necessary but not

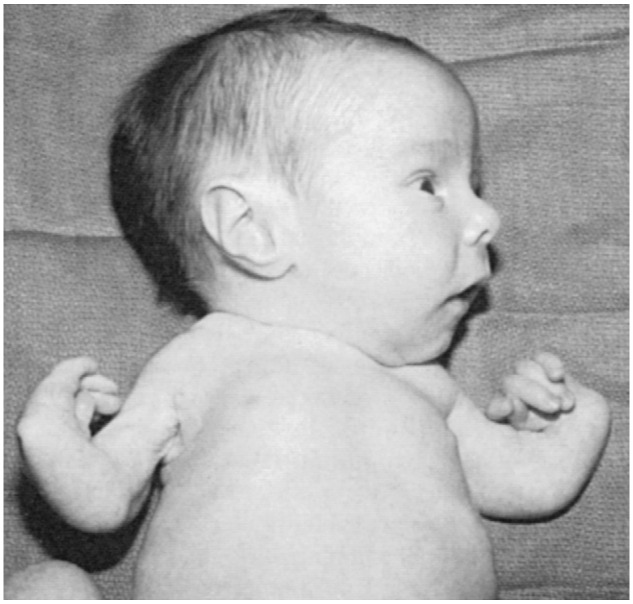

Figure 46–15. Patient with thrombocytopenia with absent radii syndrome.

sufficient to cause the disease.[43] Inheritance of an additional modifier is required to cause the phenotype, although the nature of this modifier is unknown.

Radial abnormalities are a sine qua non in TAR. In a patient with TAR, thumbs may be present in the absence of radii, whereas in Fanconi anemia, absence of the radius always is accompanied by thumb abnormalities. Despite these differences in clinical presentation, it is prudent to test patients who have a clinical picture of TAR for increased chromosome fragility to formally rule out Fanconi anemia.

Fanconi Anemia

See earlier discussion.

Although the phenotypes of TAR and Fanconi anemia overlap somewhat, several features distinguish these conditions. Cytopenias in the autosomal recessive disorder Fanconi anemia rarely present in the neonatal period, but the associated dysmorphic features such as hypopigmented skin lesions, café-au-lait spots, thumb abnormalities, short stature, microcephaly, and genitourinary abnormalities may be evident. Only about 30% of patients with Fanconi anemia have radial anomalies, whereas absent radius is always present in TAR. Fanconi patients develop progressive bone marrow failure as children or adults. Fanconi anemia patients have a cancer predisposition that is not affected by hematopoietic stem cell transplantation and correction of bone marrow failure.

X-Linked Thrombocytopenia with Dyserythropoiesis and Cryptorchidism

Boys with X-linked thrombocytopenia with dyserythropoiesis and cryptorchidism have a point mutation in the gene encoding GATA1, a transcription factor expressed in megakaryocytes, erythroid precursors, and Sertoli cells.[32] This mutation disrupts the interaction of GATA1 with the nuclear coactivator FOG1. The bone marrow from these patients is hypercellular and contains numerous small, dysplastic megakaryocytes.

CONGENITAL QUALITATIVE DEFECTS IN PLATELET FUNCTION

Glanzmann Thrombasthenia

Glanzmann thrombasthenia is an autosomal recessive condition caused by a deficiency in the platelet fibrinogen receptor GP IIb-IIIa.[61] This protein complex, a member of the integrin family of adhesion proteins, is also referred to as α-IIIb-β-III integrin. This complex is abundantly expressed on the surface of platelets. Each of the two subunits of the platelet fibrinogen receptor is encoded by a separate gene, and these genes are closely linked on chromosome 17. Patients with Glanzmann thrombasthenia exhibit decreased expression of functional GP IIb-IIIa on the platelet surface secondary to mutations in either the GP IIb or GP IIIa gene. These patients have mucocutaneous bleeding in the neonatal period and remain predisposed to bleeding throughout their lives.

Platelet counts and morphology are normal. The bleeding time is prolonged, although this test is notoriously difficult to perform and interpret in neonates. Clot retraction, which depends on platelet-platelet interactions, is abnormal in Glanzmann thrombasthenia and is a useful laboratory screening test, even in neonates. Abnormal platelet aggregation is seen in response to a variety of agonists, including collagen, adenosine diphosphate, epinephrine, arachidonic acid, and thrombin. GP IIb-IIIa levels on platelets of suspected patients can be measured by flow cytometry.

Bleeding in patients with Glanzmann thrombasthenia can be managed with platelet transfusions. However, platelet transfusions should be reserved for severe episodes of hemorrhage because high-titer alloantibodies that recognize GP IIb-IIIa can develop in these patients, making subsequent platelet transfusions less efficacious. Patients with Glanzmann thrombasthenia generally survive into adulthood.

Paris-Trousseau Syndrome

Paris-Trousseau syndrome is characterized by congenital thrombocytopenia, giant platelet α-granules, and a deletion at chromosome 11q23.[46] The thrombocytopenia reflects defective megakaryocyte maturation. Numerous micromegakaryocytes can be seen in the bone marrow. Congenital malformations, including facial dysmorphism and cardiac anomalies, can accompany the hematopoietic defects.

OTHER QUALITATIVE DEFECTS IN PLATELET FUNCTION

Patients with the autosomal recessive conditions Hermansky-Putlak and Chédiak-Higashi syndromes have albinism and a mild bleeding tendency secondary to abnormalities in platelet granules.

THE CONGENITAL MACROTHROMBOCYTOPENIA SYNDROMES

Bernard-Soulier Syndrome

Patients with Bernard-Soulier syndrome have a deficiency in the platelet vWF receptor, a complex structure that contains four proteins designated GP Ib-α, GP Ib-β, GP IX, and GP V. Mutations in the genes encoding GP 1b-α, GP 1b-β, and GP IX have been associated with the syndrome. The GP Ib-α-Ib-β-IX-V complex mediates adhesion of platelets to vWF deposited on vascular subendothelium (see Fig. 46-10).

The platelets in Bernard-Soulier syndrome patients are unusually large, approaching the size of mature lymphocytes. It is not clear why Ib-α-Ib-β-IX-V deficiency results in increased platelet size.

Bernard-Soulier syndrome is inherited as an autosomal recessive trait, and patients can have moderate to severe bleeding. The diagnosis is confirmed by failure of platelets to agglutinate in the presence of ristocetin, which induces binding of vWF to the glycoprotein complex. Agglutination in response to other agonists is normal.

May-Hegglin Anomaly

This autosomal dominant defect is known for giant platelets and moderate thrombocytopenia (macrothrombocytopenia) and leukocyte inclusions.

Alport Syndrome (Hereditary Nephritis) and Epstein Syndrome

Familial hematuria, progressive renal failure, deafness, and ocular abnormalities characterize the classic presentation of this syndrome. Some families with Epstein syndrome have a moderate macrothrombocytopenia with leukocyte inclusions.

NEOPLASMS IN THE NEONATE

The peak incidence of cancer in childhood (<15 years of age) occurs during the first year of life. The annual incidence rate for all cancers of infancy is 233 per million infants, according to the National Cancer Institute's statistics for the years 1976 to 1984 and 1986 to 1994. This represents 10% of all childhood malignancies. Figure 46-16 provides a graphic summary of cancer incidence by common types. In adults, cancer is thought to occur after a long interplay between environmental triggers and genetic predisposition. In infancy, especially in the neonatal period, cancer includes a rare spectrum of diseases in which the normal, genetically programmed protections against unregulated growth of cells fail very early. Researchers studying infant cancers may provide the clearest information about oncogenesis. The first year of life is the only time in childhood when the incidence of cancers is not higher in males than females, but is instead equal. Overall, the prognosis for infants compared with older children with the same histologic diagnoses is worse, despite the fact that infant neuroblastoma has a much superior survival rate. Many entities (e.g., retinoblastoma [see also Chapter 53], Wilms tumor [see also Chapter 51], and brain tumors [see also Chapter 40]) are discussed elsewhere.

Neuroblastoma

About half of infant neuroblastomas are diagnosed within the first 4 months of life. These tumors of neural crest origin can arise anywhere along the sympathetic chain. In infants, the most common sites of presentation are cervical and thoracic. Involvement of the adrenal gland, which presents as an abdominal mass, is most common in older children. Neuroblastomas can be detected by prenatal ultrasound. Many of these tumors secrete catecholamines, so urine homovanillic acid and vanillylmandelic acid levels are commonly used diagnostic tests. Mass infant screening programs using these urine tests in Japan, Quebec, and Europe have increased the detection of good-prognosis tumors, but have failed to change the mortality rate from high-risk neuroblastoma.

The most important variables for prognosis for infant neuroblastoma are the patient age at diagnosis, the stage of the tumor, DNA index, and *MYCN* amplification. Tumor hyperdiploidy (DNA index >1) is a favorable prognostic indicator, whereas *MYCN* amplification is associated with more aggressive disease. Infants (<1 year of age) with neuroblastoma have a better prognosis than older children, with an overall 5-year survival of about 80% (versus 45% for those >1 year at diagnosis). Children younger than 1 year of age with localized tumors have a 5-year survival rate of 95%. A significant proportion of infants with metastatic disease are in the prognostically favorable stage IV-S category. These infants have liver, skin, and bone marrow involvement in addition to a seemingly localized primary tumor (<1 year), but do not have evidence of bone metastases. Despite metastatic disease, this subgroup of infants has the unique, poorly understood characteristic of spontaneous tumor regression. Surgery, chemotherapy, high-dose chemotherapy with peripheral blood stem cell rescue, and radiation therapy are treatment options, depending on risk group. Infants with low-risk disease may be candidates for observation with close monitoring for resolution.

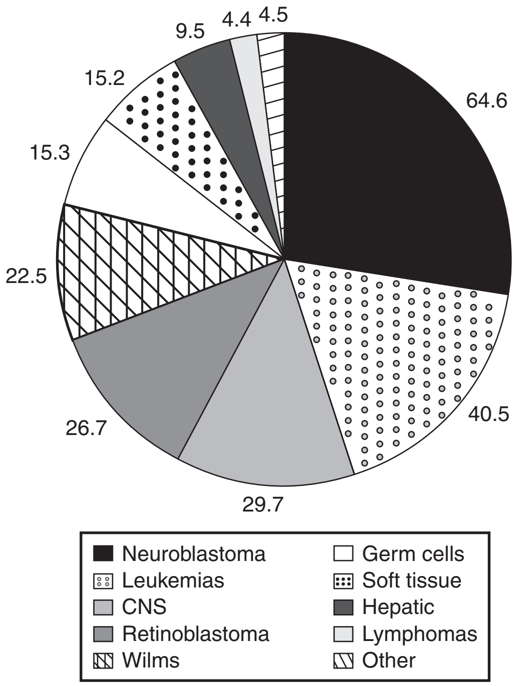

Figure 46–16. Average annual incidence per 1 million infants of cancers by type, SEER data, 1976-1984 and 1986-1994. *(Adapted from Gurney JG, et al: Cancer among infants. Available at: www.SEER.cancer.gov/publications.childhood/infant.pdf. 1999.)*

Infant Leukemia

Infant leukemias tend to present toward the second half of the first year of life. A number of clinical features that have been associated with a poorer prognosis are common in neonates and infants with acute lymphocytic leukemia (ALL): a large tumor cell burden (hyperleukocytosis), massive hepatosplenomegaly, involvement of the central nervous system, and hypogammaglobulinemia. The leukemic blasts in infant ALL often are CD10 negative, and cytogenetic abnormalities involving the *MLL* (mixed lineage leukemia) gene at chromosome 11q23 are common. Although neonates experience significant toxicities both from chemotherapy and central nervous system irradiation, the especially poor prognosis for infant ALL is due to the high incidence of bone marrow and extramedullary relapse. Progressively more intensive chemotherapeutic regimens and bone marrow transplantation have been used in these patients, but the event-free survival rate at 5 years is only in the 30% range.

In contrast to ALL, infants with acute myelogenous leukemia (AML) have similarly poor remission and disease-free survival rates indistinguishable from those for older children. Distinctive features of AML in the infant include very high incidences of cutaneous involvement (leukemia cutis) and central nervous system disease, hyperleukocytosis, and an unusually high number of cases with blasts of the monoblastic or myelomonocytic type. Cytogenetic abnormalities in the blasts are exceptionally common. Infants with Down syndrome who are diagnosed with AML have a superior survival rate compared with others with AML because they tend to develop the acute megakaryocytic leukemia subset of AML (AMKL) and have a very high response rate to therapy.

Juvenile myelomonocytic leukemia (JMML; formerly juvenile chronic myelogenous leukemia), is a myeloproliferative disorder that accounts for about 1% of pediatric leukemias. Ten percent of cases are diagnosed before 3 months of age. Clinical manifestations include splenomegaly, rash, lymphadenopathy, failure to thrive, leukoerythroblastosis, monocytosis, thrombocytopenia, and elevated fetal hemoglobin. The abnormal growth of JMML cells has been linked to a dysregulated transduction signal through the pathway that involves GM-CSF, the GM-CSF receptor neurofibromin, and Ras. When cultured in vitro, JMML cells exhibit a hypersensitivity to GM-CSF. PTEN protein deficiency has been noted in a large number of patient leukemia cells tested and may explain the lack of negative growth signals that should counteract hyperactive Ras signaling.

About 15% to 20% of children with JMML have neurofibromatosis type I. *RAS* family oncogene mutations occur in the leukemia cells in 25% of sporadic JMML cases. Patients with Noonan syndrome, a disorder associated with gain-of-function mutations in *PTPN11*, the gene encoding the protein tyrosine phosphatase SHP-2, are at increased risk for developing JMML. Mutations in *PTPN11* are present in the leukemia cells of one third of spontaneous JMML cases. Patients diagnosed before 2 years of age and those with Noonan syndrome have a better prognosis. Although a variety of therapies have been employed to treat JMML, allogeneic bone marrow transplantation is the only curative treatment.[28]

Congenital Leukemia

Although rare (<5 cases per 1 million live births), leukemia can manifest in the newborn period. Associations between congenital defects or chromosomal abnormalities and congenital leukemia have been made. Eighty percent of congenital leukemias are nonlymphocytic. The infant may be symptomatic at the time of birth or may be diagnosed later in the neonatal period. It is often difficult to distinguish leukemia from a leukemoid reaction (see earlier) secondary to infection or associated with Down syndrome. Infiltration of nonhematopoietic organs by hematopoietic blasts and cytogenetic abnormalities (other than trisomy 21) in the blasts differentiates leukemia from the more benign processes. With the exception of Down syndrome patients with AMKL, congenital leukemia carries a grave prognosis.

Transient Myeloproliferative Disorder

See “Down Syndrome,” earlier.

Teratomas and Other Germ Cell Tumors

Most infant germ cell tumors are diagnosed before the age of 2 months. Germ cell tumors originate early in life from preinvasive precursors that transform into overt tumors during infancy, adolescence, or young adulthood.[38] Whereas 90% of germ cell tumors diagnosed during adult life are gonadal, two thirds of childhood germ cell tumors are extragonadal. Most neonatal germ cell tumors, irrespective of location, are benign.

Teratomas are the most common neonatal germ cell tumors.[38] The term *teratoma* describes both benign and malignant tumors composed of haphazardly intermixed tissues that originate from pluripotent stem cells and are foreign to the anatomic site in which they arise. Traditionally, tissue components from all three embryonic germ layers—endoderm, mesoderm, and ectoderm—should be represented in a teratoma. However, it is now generally accepted that tumors that are foreign to the site where they arise and consist of more than one embryonic layer can be classified as teratomas.

Sacrococcygeal teratomas are frequently detected at birth as a mass in the region of the sacrum or buttocks, sometimes accompanied by obstruction of the rectum or urinary tract. These tumors are most often postsacral but occasionally presacral. Vertebral anomalies can be seen in patients with sacrococcygeal teratomas.

The mainstay of therapy for germ cell tumors is surgical resection. Typically, teratomas have an excellent outcome. Immature teratomas have a prognosis comparable to mature teratomas, provided the tumor can be totally excised. In the case of sacrococcygeal teratomas, prematurity, perioperative hemorrhage, and other postoperative events result in a 10% to 20% risk for mortality. Endodermal sinus tumors of the infant testis have a better prognosis than those at later ages and other locations, including the ovary. See Table 46-22 for age-adjusted α-fetoprotein values.

TABLE 46–22 Postnatal Serum Concentrations of α-Fetoprotein in Preterm and Term Infants

	AFP CONCENTRATION (μg/L)*		
Age	*10th percentile*	*Median*	*90th percentile*
Preterm Infants (27-35 Weeks' Gestational Age)			
Birth	149,700	252,125	335,375
1 wk	43,825	96,510	234,500
1 mo	21,825	41,975	66,460
2 mo	3,100	16,000	36,900
3 mo	560	1,250	10,140
4 mo	75	162	621
6 mo	22	67	170
9 mo	6	20	54
12 mo	5	10	28
Term Infants (38-42 Weeks' Gestational Age)			
Birth	17,200	30,875	44,350
2 mo	88	206	412
4 mo	16	77	127
6 mo	11	30	67
9 mo	5	12	27
12 mo	4	7	17

Infantile Myofibromatosis

Infantile myofibromatosis generally occurs in the newborn period and is the most common fibrous tumor of infancy.[73] The disease can manifest as a solitary lesion or multiple lesions in the skin, subcutaneous tissue, skeletal muscle, bone, or viscera such as the lung. Histopathology reveals a spindle cell neoplasm with myofibroblastic proliferation. A unique feature of the neoplasm is its ability to spontaneously regress. The multifocal form of the disease may be associated with a high morbidity and mortality if visceral involvement is evident. Autosomal dominant inheritance has been reported in some cases.[2] Treatment depends on the location of the tumors, with surgery or chemotherapy reserved for rapidly progressive or symptomatic disease.[73]

Congenital Fibrosarcoma

Congenital fibrosarcoma is a spindle cell tumor of the soft tissues. It usually presents before the age of 2 years. Surgery is the mainstay of therapy. Although these malignancies can recur locally, they have a generally favorable prognosis and only rarely metastasize. A novel chromosomal translocation, t(12;15)(p13;q25), which gives rise to an *ETV6-NTRK3* gene fusion, is present in these tumors. Polymerase chain reaction–based assays for this fusion protein are helpful in making this diagnosis and in differentiating this tumor from composite infantile myofibromatosis.[2]

Rhabdomyosarcoma

Rhabdomyosarcoma is a tumor of striated muscle cell origin that rarely occurs in the neonate. Neonatal rhabdomyosarcoma usually occurs in the abdomen or pelvis, rather than appearing as masses in the head and neck region, as is common in older patients. The prognosis depends on both the histologic type (embryonal, alveolar, botryoid, and pleomorphic in best to worst order of prognosis) and the extent of tumor resection. Both radiation therapy and chemotherapy are important adjuvants to surgical resection.[72]

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis is a rare disorder, primarily of childhood, characterized by the infiltration of tissues with histiocytes. Histiocytosis can be present at birth, although the peak age of incidence is between 1 and 3 years of age. Langerhans cell histiocytosis includes localized and disseminated forms of disease. An isolated bone lesion (most commonly skull) is an example of low-risk disease that requires only observation. The disseminated form, formerly termed *Letterer-Siwe disease*, is often seen in infants and children younger than 2 years of age and manifests with rash, lymphadenopathy, fever, and wasting. Involvement of at-risk organs (lungs, liver, spleen, and bone marrow) portends a poor prognosis. High-risk disease is treated with chemotherapy. Multifocal bone lesions and those occurring in the so-called special sites, such as intraspinal or parameningeal, also require chemotherapy.[78]

Hemophagocytic Lymphohistiocytosis Syndrome

Hemophagocytic lymphohistiocytosis is a rare disease, generally affecting infants and children, which causes persistent T-cell activation and histiocytic infiltration of tissues. It is estimated to occur in 1.2 per 1 million children. A primary form, also known as *familial hematophagocytic lymphohistiocytosis*, is an autosomal recessive disease associated with mutations in the perforin genes (*PRF1* and *UNC13D*), a gene involved in T-cell cytotoxicity (*MUNC13-4*), and the syntaxin 11 gene (*STX11*). The secondary form of the disease occurs in response to viral, bacterial, parasitic, or fungal infections, as well as cancers and rheumatologic disorders. Immune dysregulation, characterized by reduced or absent natural killer cell function, is present in most cases. Usually, infection will trigger an inflammatory process that abates with control of the infection. In hemophagocytic lymphohistiocytosis, immune dysregulation results in persistence of the inflammatory response. Common clinical features include persistent fever, thrombocytopenia, hepatosplenomegaly, a cutaneous maculopapular eruption, and central nervous system involvement. Laboratory findings include thrombocytopenia, very elevated ferritin level, anemia, hypofibrinogenemia, neutropenia, and cerebrospinal fluid pleocytosis. Biopsy of tissue, commonly bone marrow, will show phagocytosis of blood cells. Specialized tests for NK-cell function, perforin expression in lymphocytes, and genetic testing for the known mutations aid the diagnosis. The management of familial hemophagocytic lymphohistiocytosis should include genetic testing and counseling of family members. Without treatment, the familial syndrome is rapidly fatal. Chemotherapy can be used as a temporizing measure, but cure requires allogeneic bone marrow transplantation.[5]

PART 2

Blood Component Therapy for the Neonate

Ross Fasano and Naomi L. C. Luban

SPECIAL CONSIDERATIONS FOR TRANSFUSION THERAPY IN THE NEONATE

Neonates constitute one of the most heavily transfused patient groups in the hospital. Neonatal transfusion practices differ substantially from adult and pediatric transfusion practices owing to unique differences in neonatal physiology. Neonates have small blood volumes compared with older children and adults but high blood volume per body weight. Their immature organ system function predisposes them to metabolic derangements from blood products and additive solutions and to the infectious and immunomodulatory hazards of transfusion, such as transfusion-transmitted cytomegalovirus (TT-CMV) infection and transfusion-associated graft versus host disease (TA-GVHD). Neonates undergo rapid growth but have a limited capacity to expand their blood volume. In addition, passive transfer of maternal antibodies to the immunologically naive newborn creates unique compatibility scenarios not commonly seen in children or adults. Their responses to stresses, including hypothermia, hypovolemia, hypoxia, and acidosis, are dependent on gestational age, birthweight, and comorbidities. These considerations necessitate special approaches to transfusion therapy in the neonate.[24,35]

RISKS OF TRANSFUSION THERAPY

Advances in donor recruitment and blood screening and processing have decreased the risks associated with blood transfusion. Current transfusion considerations and guidelines focus on reducing both transfusion number and donor exposures. Nevertheless, hematologic, immunologic, infectious, cardiovascular, and metabolic complications can occur. Many of these risks exist for transfusion recipients of any age, whereas others pose a greater threat to the neonatal recipient. These potential risks affect the choice and processing of blood products. Parents must be advised of the risks, benefits, and alternatives to transfusion, and informed consent should be documented in the medical record along with the indications for and results of the prescribed transfusion.

Metabolic Complications

Neonates, especially extremely premature infants, are more susceptible to metabolic alterations because of the immaturity of many of their organ systems. Glucose imbalances, hyperkalemia, and hypocalcemia are the most common metabolic derangements related to transfusion resulting from the inability of the infant to efficiently metabolize or excrete many compounds within the blood components such as anticoagulants, preservatives, and other solutes.

HYPOGLYCEMIA

See also Chapter 49, Part 1.

Hypoglycemia can result from the combination of decreased glucose infusion rates during transfusion and impaired glycogenolysis and gluconeogenesis within the liver of the preterm neonate. Continuous glucose infusion rates of more than 3 to 4 mg/kg per minute are often required in preterm infants; if maintenance fluids are suspended during transfusion, glucose infusion rates can decrease to about 0.2 mg/kg per minute for citrate-phosphate-dextrose-adenine preserved (CPDA-1) red blood cells (RBCs) and to 0.5 mg/kg per minute for Adsol preserved (AS-1) RBCs. In a previous report of 31 fresh (<5 days old) small-volume RBC transfusions in 16 preterm infants (mean birthweight and gestational age, 863 g and 26 weeks, respectively), 15% of infants receiving AS-1 preserved RBCs and 64% of infants receiving CPDA-1 preserved RBCs required supplemental dextrose infusions during the transfusion because of hypoglycemia (blood glucose <35-40 mg/dL or symptoms of hypoglycemia).[21] Subsequent analysis has shown similar frequency of transfusion-associated hypoglycemia when older (5 to 21 days old) AS-1 preserved units were used. Furthermore, reported incidences of hypoglycemia in neonates either during or after exchange transfusions range from 1.4% to 3.6% with no difference in incidence when group O whole blood or reconstituted whole blood was used. Hypoglycemia occurring after exchange transfusion is believed to be due to intraprocedural hyperglycemia, which causes rebound hypoglycemia from insulin secretion.[45] Preventive measures for transfusion-associated hypoglycemia include recognizing those infants at risk for developing glucose homeostatic imbalances, continuing the infusion of maintenance fluids rich in dextrose (albeit at a slower rate) in order to maintain an adequate glucose infusion rate during simple transfusions, and close monitoring of blood glucose during both small and large volume transfusions.

HYPERKALEMIA

As stored RBCs age, potassium leaks out into the plasma and raises the extracellular potassium level within the component. RBC units in extended-storage media (AS-1, AS-3, AS-5) have a hematocrit (Hct) of about 60%, and RBCs stored in CPDA have an Hct of about 70%. Furthermore, some pediatric transfusion centers centrifuge RBC aliquots before transfusions for neonates to further reduce the plasma component to 20% (i.e., RBC unit: Hct >80%). After 42 days of storage, K^+ levels in the plasma of an AS-1 preserved RBC unit approximates 0.05 mEq/mL. Therefore, infusing 15 mL/kg would yield a potassium dose of 0.3 mEq/kg (i.e., 1 kg infant receiving 15 mL RBC, 6 mL plasma). Conversely, after 35 days of storage of CPDA-1 preserved RBCs, potassium levels in the plasma approximate 0.07 to 0.08 mEq/mL. Transfusing 15 mL/kg of the CPDA-1 stored product would yield a potassium dose of 0.3 to 0.4 mEq/kg (i.e., 1 kg infant receiving 15 mL RBC, 4.5 mL plasma).[56] Given that the daily potassium requirement is about 2 to 3 mEq/kg, simple RBCs transfused slowly over 2 to 4 hours should pose no theoretical risk. It has been shown in multiple studies that transfusing dedicated RBC units to their expiration dates does not cause hyperkalemia even in extremely preterm infants.[23,30,34,45,57] Therefore, the routine practice of washing older RBCs is unnecessary for most small-volume RBC transfusions in infants, including those with birthweight less than 1.5 kg.[30]

This rationale may not apply to large-volume transfusions (>25 mL/kg) or rapid small-volume transfusions. There have been reports of hyperkalemia-induced electrocardiac abnormalities and cardiac arrest when RBC transfusions (fresh and old) have been administered through rapid infusion (10 to 20 mL/kg over 10 to 15 minutes) to neonates with concurrent low cardiac output states, when irradiated more than 24 hours before infusion, and when given by central line directly into the inferior vena cava. In cases of large-volume transfusions (i.e., exchange transfusion, cardiopulmonary bypass, and massive transfusion of neonates), fresh reconstituted whole blood (<7 days old) is often used because of concern for high potassium concentrations in older RBC units. In most cases, these RBCs are administered rapidly and in large amounts, thereby exposing the neonate to potentially toxic potassium concentrations.[34] In circumstances in which fresh reconstituted whole blood is unavailable for large-volume transfusions, saline-washed RBCs can be used.[24,34,50] Special considerations should be taken when RBCs need to be transfused rapidly, and this should be coordinated with the transfusion center so that proper preparation can be performed to avoid hyperkalemia.

HYPOCALCEMIA

See also Chapter 49, Part 2.

Infants, especially premature infants, are particularly susceptible to hypocalcemia within the first week of life owing to multiple factors. Because of the immaturity in neonatal liver and kidney function and the low amount of skeletal muscle mass, transfusion of citrate enriched blood can result in hypocalcemia from citrate toxicity. The amount of citrate infused into a neonate during a small-volume transfusion (10 to 15 mL/kg) is unlikely to cause hypocalcemia; however, the citrate load during an exchange transfusion can reach very high levels and lead to symptomatic hypocalcemia. In a retrospective review of 106 infants undergoing 140 exchange transfusions, symptomatic hypocalcemia was one of the most common serious side effects. Eighty-one infants were classified as "healthy" if indication for exchange was solely asymptomatic hyperbilirubinemia; 25 infants were classified as "ill" if comorbid conditions existed. Incidences of asymptomatic and symptomatic hypocalcemia (defined as irritability, jitteriness, or electrocardiographic changes) were 34.6% and 5%, respectively, in the "healthy" infant population, and 40% and 8%, respectively, in the "ill" infant population.[22] Because clinical manifestations of hypocalcemia are often subtle or variable in premature infants, many recommend monitoring ionized calcium levels and QT intervals throughout exchange transfusion procedures, in addition to minimizing potentiating factors such as hypomagnesemia, hyperkalemia, alkalosis, and hypothermia in high-risk (ill) patients.[45]

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

TA-GVHD occurs when an immunosuppressed or immunodeficient patient receives cellular blood products, which possess immunologically competent lymphocytes.[31] The transfused donor lymphocytes are able to proliferate and engraft within the immunologic incompetent recipient because the recipient is unable to detect and reject foreign cells. The degree of similarity between HLA antigens of donor and recipient also increases the likelihood of developing TA-GVHD. As an example, in the setting of directed donation from a first-degree relative, donor lymphocyte homozygosity for an HLA haplotype for which the recipient is haploidentical predisposes to recipient tolerance, donor lymphocyte engraftment, and alloreaction leading to TA-GVHD.[35]

The clinical signs and symptoms of TA-GVHD include fever; generalized, erythematous rash that may progress to desquamation; watery diarrhea; mild hepatitis to fulminant liver failure; respiratory distress; and pancytopenia, which is usually severe because hematopoietic progenitor cells are preferentially affected. Onset is 3 to 30 days after transfusion of lymphocyte-replete cellular blood components. Neonates at "high risk" for TA-GVHD include those with impaired cellular immunity, such as severe combined immunodeficiency disease or Wiskott-Aldrich syndrome, those receiving intrauterine transfusions or neonatal exchange transfusion, and those receiving cellular blood components from family members or those who are genetically similar to the recipient. Extremely premature neonates are also considered by many to be at significant risk for TA-GVHD.[22,56]

No effective therapy is available for TA-GVHD, and owing to bone marrow hypoplasia, the mortality rate is 90% in the pediatric population. Fortunately, this complication can be prevented by pretransfusion gamma irradiation of cellular blood components at a dose of 2.5 Gy, which effectively abolishes lymphocyte proliferation.[31] The shelf life of irradiated RBCs is 28 days; however, no data currently exist on the safety in the neonatal population of gamma-irradiated RBCs that are stored for this amount of time. Because potassium and free hemoglobin increase after irradiation and storage of RBCs, it is preferable to irradiate cellular blood products close to administration time for neonates, who may not be able to tolerate high potassium loads.[17] There exists no "standard of care" regarding irradiation of blood products for otherwise not high-risk infants. Many transfusion centers irradiate all cellular blood products given to preterm infants born weighing 1.0 to 1.2 kg or less, whereas some neonatal centers irradiate all cellular blood products for infants younger than 4 months, citing the lack of clinical studies on the incidence of TA-GVHD in the neonatal population and the concern for failing to recognize an infant with an undiagnosed congenital immunodeficiency. When an infant requires irradiated blood components, all cellular blood components for that infant should be irradiated; however, it is not necessary to irradiate acellular blood components, such as fresh frozen plasma (FFP). The known and presumed indications for irradiation of blood components for neonates are listed in Box 46-12.

Transfusion-Associated Infections

Many infectious agents can be transmitted by blood or blood component transfusion (Table 46-23). These include viruses, bacteria, protozoa, and other pathogens. Current transfusion-transmitted disease testing for allogeneic blood donation include hepatitis B surface antigen (HBsAg), hepatitis B core antibody (anti-HBc), anti-hepatitis C antibody (anti-HCV), antibody to HIV-1 and HIV-2 (anti-HIV-1/2), antibody to HTLV-I and HTLV-II, serology for syphilis and *Trypanosoma cruzi*, and nucleic acid testing (NAT) for HIV-1, HIV-2, HCV, and West Nile virus (WNV).[46]

CYTOMEGALOVIRUS

The prevalence of human CMV is 30% to 70% in blood donors and varies based on demographic differences within areas of the United States. This DNA virus remains latent within the leukocytes of immune persons and can be transmitted by transfusion of cellular blood components into seronegative recipients. Primary CMV infection occurs in a seronegative recipient from a blood component from a donor who has either active or latent infection. There is wide variation in clinical sequelae from transfusion-transmitted CMV (TT-CMV), ranging from asymptomatic serologic conversion to significant morbidity and mortality from CMV-related pneumonia, cytopenias, and hepatic dysfunction. Premature

BOX 46–12 Indications for Administering Irradiated Blood Components to Neonates

- Transfusion to a premature infant with birthweight <1200 g
- Intrauterine transfusion
- Known or suspected congenital cellular immunodeficiency
- Significant immunosuppression related to chemotherapy or radiation treatment
- Transfusion of a cellular blood component obtained from a blood relative
- Transfusion of an HLA-matched or platelet crossmatched product

Modified from Josephson CD: Neonatal and pediatric transfusion practice. In Roback JD, editor: *Technical manual of the American Association of Blood Banks*, 16th ed, Bethesda, MD, 2008, American Association of Blood Banks, pp 639-663; and Roseff SD, et al: Guidelines for assessing appropriateness of pediatric transfusion, *Transfusion*, 42:1398, 2002.

TABLE 46–23 Transfusion-Transmitted Infections

Infectious Agent	Infectious Risk
Bacterial contamination	(*Yersinia enterocolitica, Escherichia coli, Brucella* species)
Platelets	1 in 5000
Red blood cells	1 in 5 million
Hepatitis A	1 in 10 million
Hepatitis B	1 in 250,000 to 350,000
Hepatitis C	1 in 1.8 million
Human immunodeficiency virus	1 in 2.3 million
Cytomegalovirus	Unknown
Human T-cell lymphotrophic virus	1 in 641,000 to 921,000
West Nile virus	Extremely low
Chagas disease (*Trypanosoma cruzi*)	Extremely low*
Syphilis	Virtually nonexistent
Malaria	1 in 4 million
Babesiosis (*Babesia microti*)	Extremely low†
Creutzfeldt-Jakob disease	No cases reported in United States

*Although about 1 in 25,000 to 50,000 U.S. donors are seropositive, only 7 cases of transfusion-transmitted *T. cruzi* have been reported in the United States and Canada.

†May be as high as 1 in 1800 in highly endemic areas (Northeast United States).

Data from references 5, 18, and 35.

seronegative neonates weighting less than 1250 g, fetuses receiving intrauterine transfusions, severely immunocompromised individuals, and recipients of hematopoietic stem cell and solid-organ transplants are recipient groups at increased risk for post-transfusion CMV-related morbidity and mortality.[35] Infants born to seropositive mothers apparently have decreased risk for acquiring TT-CMV, but perinatal infection with a different strain of CMV has been reported infrequently.

Because the prevalence of CMV seropositivity among blood donors limits the availability of seronegative components, supplementary strategies can be used to minimize the risk for TT-CMV infection in high-risk infants. Use of third-generation leukoreduction filters at the time of collection of cellular products has been recommended for recipients at risk for TT-CMV. The American Association of Blood Banks states that leukoreduced blood products must contain fewer than 5×10^6 total WBCs per unit. Current third-generation leukocyte reduction filters consistently provide WBC reduction in accordance with these standards, with some filters yielding less than 1×10^6 per product. European standards maintain a more stringent definition of leukoreduced as less than 1×10^6 total WBCs per unit.[35]

Leukocyte reduction has been shown to be effective in preventing CMV infection in neonates, among other groups; however, whether leukocyte reduction is as efficacious as the use of CMV-seronegative blood has been disputed widely. In one study, equivalent rates of post-transfusion CMV infection in allogeneic hematopoietic stem cell transplant recipients were found for CMV-seronegative units and leukoreduced units (1.4% versus 2.4%, respectively).[12] A subsequent study demonstrated similar rates of TT-CMV for leukoreduced and CMV-seronegative platelet products, but not for RBC products.[42] No formal consensus on the debate of equivalency has been developed, leading many to advise against the elimination of “dual inventories” of blood products for CMV-seronegative and seropositive units. Nonetheless, variable strategies for preventing TT-CMV currently exist depending on the number of high-risk patients treated at a given center, the regional donor demographics, and product availability.

HEPATITIS A VIRUS

Post-transfusion hepatitis A infection is an infrequent complication of transfusion because of the short period of viremia and the lack of an asymptomatic carrier state associated with the hepatitis A virus.[19] The risk for hepatitis A transmission increases when the transfused product is derived from a pool of products, such as cryoprecipitate and plasma-derived clotting factors. Purification processes used to treat derivatives of human plasma are ineffective against nonenveloped viruses such as hepatitis A.

HEPATITIS B VIRUS

Acute infection with hepatitis B virus (HBV) is symptomatic in about 50% of adults, and 5% to 10% of those infected become chronic carriers.[19] In contrast, HBV infection acquired in infancy and early childhood is often asymptomatic, yet 70% of those infected become chronic carriers. Elimination of paid blood donors, uniform screening of blood donations for HBV surface antigen (HBsAg), and routine immunization for hepatitis B have reduced the estimated incidence of transfusion-transmitted HBV (TT-HBV) to 1 in 150,000 to 300,000 units transfused. The residual risk for TT-HBV is attributed to infection from units of donors who donated within the HBsAg-negative window of early infection, donors who are chronic carriers with a level of HBsAg below the level of detection, and donors infected with a mutant strain of HBV that is not detected by current testing.[18]

HEPATITIS C VIRUS

Hepatitis C virus (HCV) is a well-known cause of transfusion-associated hepatitis. Acute HCV infection is often asymptomatic and anicteric, but the likelihood of developing chronic hepatitis exceeds 60%. About 20%-30% of those with untreated chronic hepatitis develop hepatic fibrosis and cirrhosis within two decades; those with cirrhosis have a 1% to 5% risk for hepatocellular carcinoma 20 years after cirrhosis is diagnosed.[35] Long-term outcome is dependent on the route of transmission, age when infected, sex, and coexisting morbidities. A retrospective study of 31 adults with transfusion-associated HCV acquired at birth (35 years earlier) described a milder disease with slower progression to hepatic fibrosis in perinatally acquired HCV compared with those who acquire HCV in early adulthood.[15,33] In a recent lookback study involving previously transfused infants and children, 88% of those with silent infection (positive anti-HCV enzyme immunoassay) had persistent HCV viremia 10 years after transfusion. This is in contrast to previously reported pediatric HCV clearance rates of 45% and 42% 19.5 and 35 years after transfusion, respectively, which indicated that children, unlike adults, may clear HCV over time.[33] Pediatric clinical trials are underway to determine the implications of early identification of those with silent HCV infection and the impact antiviral therapy may have on viral clearance and prevention of the long-term effects of HCV infection.

Since the advent of nucleic acid testing (NAT) for HCV in the late 1990s, the incidence of TT-HCV has decreased to 1 in 1.8 to1.9 million within the United States. This is due to shorter window periods from time of acute infection to laboratory markers of infection (16 to 32 days) within the donor population.[18,35]

HUMAN IMMUNODEFICIENCY VIRUS TYPES 1 AND 2

The retroviruses HIV-1 and HIV-2 are the agents responsible for AIDS. In the United States, most AIDS cases are related to HIV-1. About 1.9% of all reported cases of AIDS have been attributed to HIV-1 transmission by blood components, excluding factor concentrates.[18,35] Factor concentrates were responsible for an additional 0.75% of the more than 339,000 reported transfusion-transmitted AIDS cases. Virtually all these transfusion-transmitted infections occurred before 1985, when serologic screening for HIV was initiated, and numerous effective methods of viral inactivation for plasma-derived clotting factor concentrates subsequently became available. Today, the risk for HIV transmission from blood transfusion is less than 1 in 2.1 million owing to improved donor history screening and the advent of NAT testing in the late 1990s, which decreased the estimated window period to 12 to 13 days.[1]

EMERGING PATHOGENS

West Nile virus (WNV), a mosquito-borne, single-stranded RNA virus of the Flaviviridae family, has become a major public health concern since its first detection in the United States in 1999. The first cases of transfusion-transmitted WNV occurred in 2002, with growing numbers of cases through 2004. Infection results in neuroinvasive disease (meningoencephalitis, spastic paralysis) in roughly 20% of individuals, with more severe sequelae in elderly and immunocompromised patients. WNV NAT testing was implemented in 2003, and since being implemented through 2004, more than 1000 blood components from 519 WNV-positive donors have been identified, preventing release.[55] There have been 9 WNV transfusion transmissions since WNV NAT implementation, representing window period donations.[5]

Continuous attention is being paid to emerging infections such as WNV, *T. cruzi*, babesiosis, variant Creutzfeldt-Jakob disease, and malaria, among others. Despite extensive donor screening and laboratory testing, infections can still be transmitted through blood products. Pathogen inactivation offers the advantage of eliminating the risk for infection with any nucleic acid–containing agent, which includes viruses, bacteria, protozoa, and fungi (prions excluded). However, current pathogen inactivation techniques using nucleic acid–inactivating agents are still under investigation because no single technique has proved effective for all blood components.[4,5]

Transfusion Reactions

Transfusion reactions are less common in neonates than in older children or adults. When an acute transfusion reaction occurs, it is crucial to discontinue the transfusion immediately, maintain intravenous access, and verify that the correct unit was transfused while treating the patient's symptoms. Notifying the transfusion service for further laboratory evaluation of the reaction is essential to properly classify the reaction so that the patient can be managed appropriately.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

Febrile nonhemolytic transfusion reactions (FNHTRs) are characterized by fever, chills, and diaphoresis. These reactions are believed to result from the release of pyrogenic cytokines by leukocytes within the plasma during storage. The incidence of FNHTRs has been decreased dramatically since the implementation of prestorage leukoreduction of RBCs and platelet products in 1999. Whereas FNHTRs occurred in about 10% of transfusions in the past, the incidence for all products since the introduction of leukoreduction is now 0.1% to 3% (about 0.2% for prestorage leukoreduction).[27,43] When FNHTR is suspected, the transfusion should be stopped and more serious reactions ruled out. A sample of blood from the patient may be sent to the laboratory for direct antibody testing (DAT), plasma hemoglobin quantification, serum lactate dehydrogenase level, and bilirubin level to ensure that the patient is not experiencing a hemolytic transfusion reaction. Bacterial contamination should be assessed by cultures of the transfused product and the patient's blood; empirical antibiotic therapy may be warranted. Most FNHTRs respond to antipyretics, and meperidine may be used for rigors.

The utility of premedication with antipyretics to prevent FNHTRs is controversial. Although a retrospective analysis of 385 pediatric patients receiving 7900 transfusions demonstrated no difference in the incidence of FNHTRs in those who received premedication with acetaminophen and dyphenhydramine,[54] a recent prospective, double-blind, placebo-controlled study of 315 adult oncology patients receiving

4199 transfusions revealed a marginal benefit with premedication in terms of reducing FNHTRs (0.34% for premedicated versus 0.64% for placebo; $P = 0.08$).[25]

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions (ATRs) are marked by urticaria and itching but can include flushing, bronchospasm, and anaphylaxis in severe cases. For mild or localized cases, transfusion can be continued once symptoms have subsided; however, severe allergic reactions (anaphylactoid or anaphylactic reactions) may require treatment with corticosteroids or epinephrine, or both. The same blood unit should never be restarted in severe cases, even after symptoms have abated. Leukoreduction does not decrease the incidence of ATRs, as it has for FNHTRs.[43] Premedication with antihistamines with or without steroids is recommended for ATRs. Because these reactions are caused by an antibody response in a sensitized recipient to soluble plasma proteins within the blood product, washed RBCs and platelets may be used for severe or recurrent ATRs nonresponsive to medication. Severe ATRs leading to anaphylaxis can often be due to the development of anti-immunoglobulin A (anti-IgA) antibodies in recipients who are IgA deficient. In these instances, IgA-deficient plasma products may be obtained, but they require the use of rare donor registries.[59]

HEMOLYTIC TRANSFUSION REACTIONS

Acute hemolytic transfusion reactions occur when RBCs are transfused to a recipient with preformed antibodies to antigens on the transfused RBCs. Almost all acute hemolytic transfusion reaction fatalities are the result of transfusion of ABO-incompatible blood due to clerical errors and misidentification; however, nonimmune causes of acute hemolysis may also occur. These include hemolysis from shear or heat stress, or both, imposed on erythrocytes by extracorporeal circuits, infusion devices, filters, blood warmers, or phototherapy light exposure. These reactions are characterized by fever, chills, diaphoresis, abdominal pain, hypotension, and hemoglobinuria with potential progression to disseminated intravascular coagulopathy and acute renal failure. When a hemolytic transfusion reaction is suspected, the transfusion should be immediately stopped, blood cultures (from patient and blood components) should be obtained, and the blood bank should be notified. A clerical check, blood component inspection, post-transfusion hemolysis check, and DAT should be completed by the blood bank. The patient's hemoglobin, hematocrit, serum bilirubin, lactate dehydrogenase, and urobilinogen should be monitored, and intravenous fluids should be administered to offset hypotension and ensure adequate urine output. Mannitol may be administered to force diuresis, but osmotic diuresis in neonates is controversial because of concerns about alterations in cerebral microcirculation and risk for intraventricular hemorrhage. Although infants younger than 4 months have an absence of A and B hemagglutinins and other RBC alloantibodies, maternal IgG antibodies can cross the placenta, causing hemolysis of transfused RBCs, and, therefore, should be considered when transfusing infants.[16]

Delayed hemolytic transfusion reactions occur 3 to 10 days after RBC transfusion and manifest as unexplained anemia, hyperbilirubinemia, and abdominal pain. As with acute hemolytic reactions, the diagnosis is confirmed by a positive DAT, hyperbilirubinemia, and a reduction in hemoglobin. Delayed hemolytic transfusion reactions are extremely rare in neonates because of the immaturity of the immune system. Even though there have been case reports of anti-E and anti-Kell formation in infants as young as 18 days of life, most reports have supported the infrequency of RBC alloimmunization and delayed hemolytic transfusion reactions in infants younger than 4 months.[35,58]

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) is an uncommon, potentially fatal acute immune-related transfusion reaction, which typically occurs within 4 hours of transfusion and presents with respiratory distress due to noncardiogenic pulmonary edema (normal central venous pressure and pulmonary capillary wedge pressure), hypotension, fever, and severe hypoxemia. Differentiation from transfusion-associated circulatory overload, an acute, nonimmune transfusion reaction that presents with respiratory distress, cardiogenic pulmonary edema, and hypertension due to volume overload, is important because treatments differ. Furthermore, transient leukopenia, which is commonly seen with TRALI but is absent in transfusion-associated circulatory overload, can aid in differentiation of these reactions. Symptoms of TRALI usually improve within 48 to 96 hours; however, three fourths of patients require aggressive respiratory support. Treatment is mainly supportive, including fluid or vasopressor support in the face of hypotension. Although aggressive diuresis is often required in transfusion-associated circulatory overload, this should be avoided in TRALI.[29]

Although the exact mechanism of TRALI remains uncertain, it is generally believed to be caused by the passive transmission of HLA or neutrophil antibodies directed against recipient leukocytes. These antibodies activate and sequester recipient neutrophils within the endothelium of the lungs, ultimately leading to the production of vasoactive mediators and capillary leak. Plasma products (FFP, apheresis platelets) account for most severe TRALI cases, and multiparous women are the most commonly implicated donors.[29,52] Because of these findings, various preventative measures have been adopted in the United States and elsewhere. These include the use of male-only high-volume plasma products (FFP, platelets), or the selection of donor products from donors who have a low likelihood of being alloimmunized by pregnancy or prior transfusions. Although there have been no definitive cases of TRALI documented in the neonatal population, TRALI has been well documented in children. A case has been reported of a 4-month-old girl who experienced respiratory distress, hypoxemia, hypotension, and fever within 2 hours of completion of an RBC transfusion from her mother. HLA antibodies were identified in the mother's serum, demonstrating the possible role of HLA antibodies in the pathogenesis of TRALI in the setting of a designated blood transfusion between mother and infant.[52,61]

DONOR-SPECIFIC UNITS

Autologous Red Blood Cell Transfusions

Collection of autologous umbilical cord blood was first reported in 1992. Depending on the gestational age of the infant, the umbilical cord contains 75 to 120 mL of blood.

Although the procedure has been associated with bacterial contamination rates as high as 8.6% and the smallest volumes of RBCs are collected from the most premature infants, interest in autologous collection remains.[13,32] Additional large, randomized, controlled clinical trials are needed to validate the safety and efficacy of this process. Delayed clamping of the umbilical cord of premature infants has been reported as a successful variation of autologous transfusion. Meta-analysis of 454 preterm infants showed that delayed cord clamping (>30 seconds) is safe and is associated with higher circulating blood volumes during the first 24 hours of life, decreased immediate need of blood transfusions, and a decreased incidence of intraventricular hemorrhage.[47]

Parental Blood Donation

Concern about transfusion-associated infections has encouraged directed donor blood programs, including those that allow biologic parents to serve as directed donors for their neonates. No data exist to support the contention that directed donor programs increase safety, and parental blood products are a poor choice in neonates with immune-mediated hemolysis, hemolytic disease of the newborn, or neonatal alloimmune thrombocytopenia. In these cases, transfused paternal cells express the antigens to which the mother has been sensitized and are passively transferred through the placenta to the neonate. Maternal plasma may contain alloantibodies directed against paternal RBC, leukocyte, platelet, and HLA antigens. Antileukocyte and antiplatelet antibodies have been found in 16% and 12% of mothers, respectively.[20] Transfusion of any maternal blood component containing plasma exposes the infant to these antibodies, with the potential to cause significant hemolytic, thrombocytopenic, or pulmonary reactions. Given these concerns, when parental directed donation is considered for an infant, the following recommendations should be reviewed with families and the provider[10,11]:

- All parental cellular blood components must be irradiated before transfusion to the neonate to prevent TA-GVHD.
- If maternal RBCs or platelets are transfused, they should be given as washed cells or should be plasma reduced, and irradiated.
- Fathers are not recommended as RBC donors for their newborns.
- Fathers should not donate granulocytes or platelets to their infants unless maternal serum is shown to lack lymphocytotoxic antibodies.

BLOOD PRODUCTS

Red Blood Cell Transfusion

INDICATIONS

In the first few days of life, term infants have an elevated hemoglobin concentration (14 to 20 g/dL); however, because of physiologic decreases in erythropoietin (EPO) levels, hemoglobin concentration decreases to a nadir of 10 to 12 g/dL about 2 to 3 months before beginning to rise. This is referred to as the *physiologic anemia of infancy*. In preterm infants, this anemia is more significant with mean nadirs of 8 g/dL in infants with very low birthweight (1.0 to 1.5 kg), and 7 g/dL in infants with extremely low birthweight (<1 kg). This is the result of lower hemoglobin concentrations at birth, frequent blood sampling, low total blood volume-to-sampling ratio, increased risk for other comorbidities, and diminished capacity of the premature infant to increase EPO.[11] Normal ranges of hemoglobin and hematocrit have been established for term and premature infants; however, guidelines for RBC transfusion therapy remain controversial because there are few randomized controlled studies that address appropriate neonatal transfusion triggers. Current guidelines for replacement transfusion therapy in neonates are given in Box 46-13. Infants with significant cardiac or respiratory disease generally receive more aggressive RBC transfusion therapy.[51,60] Two recent studies attempted to address high versus low threshold transfusion guidelines based on level of respiratory support in infants with very low or extremely low birthweight. Although very different in design and outcome, neither study clearly established an appropriate hemoglobin target. Although the multi-institutional Canadian Premature Infants in Need of Transfusion study[28] demonstrated no advantage for liberal transfusion practices, the Bell and colleagues' study[9] suggested that restrictive transfusion was associated with more apneic episodes, intraparenchymal brain hemorrhage, and periventricular leukomalacia. The question of long-term neurodevelopmental outcome is how being addressed in both infant study groups.[60]

Most RBC transfusions in newborns are administered to either replace blood loss or treat anemia of prematurity. Blood loss can result from hemorrhage or phlebotomy. Iatrogenic losses from phlebotomy can be considerable but can be minimized by judicious testing strategies, sampling from indwelling catheters, using microtainers for laboratory assays, and implementing point-of-care testing.

The use of recombinant human EPO has been proposed to decrease neonatal transfusion burden, donor exposure, anemia of prematurity, and other comorbidities. Meta-analysis of late (>8 days of life) EPO use involving 1302 preterm infants showed no clear benefit in terms of significantly decreasing

BOX 46–13 Guidelines for Red Blood Cell Replacement

IN HIGH-RISK NEONATES

- For severe cardiopulmonary disease*
  Maintain hematocrit >40%-45%
- For moderate cardiopulmonary disease:
  Maintain hematocrit >30%-35%
- For major surgery:
  Maintain hematocrit >30%-35%
- For infants with stable anemia†:
  Maintain hematocrit >20%

---

*Severe cardiopulmonary disease defined as: requiring mechanical ventilation with >0.35 F_{IO_2}.

†Especially if unexplained breathing disorders, tachycardia, or poor growth.

Modified from Strauss RG: How I transfuse red blood cells and platelets to infants with anemia and thrombocytopenia of prematurity, *Transfusion,* 48:209, 2008; and Widness JA: Treatment and prevention of neonatal anemia, *NeoReviews,* 9:e526, 2008.

donor exposures, nor was there any effect on incidence of comorbidities. Although late administration of EPO reduced the number of RBC transfusions per infant and the total transfused volume of RBCs per infant, the clinical impact of these results is trivial (<1 transfusion per infant and 7 mL/kg of RBCs). Avoiding the use of RBC transfusions was not demonstrated because many infants had received one or more transfusion prior to receiving EPO at study entry.[2] A subsequent meta-analysis designed to assess the effectiveness and safety of early initiation of EPO (<8 days of life) in 1825 premature infants also showed no evidence of any substantial benefits with regard to donor blood exposure; however, a statistically significant increased risk for retinopathy of prematurity (higher than stage 3) was noted in neonates who received early EPO therapy. Again, RBC transfusion was not avoided when RBC transfusion before study entry was considered.[36,41] Therefore, no conclusive evidence currently exists that either early or late EPO use offers any clear benefit in regard to donor exposure or improvement of morbidity or mortality in preterm infants, and that early EPO use may increase risk for retinopathy of prematurity in the neonatal population with very low birthweight. The use of EPO as a neuroprotectant is under investigation.

PRETRANSFUSION TESTING

Before RBC transfusion, a blood sample is obtained for ABO and Rh determination (blood group and type) and to screen for antibodies against blood group antigens.[46] Because antibodies identified in the neonate's blood are most often of maternal origin, maternal blood can often serve as the source of serum and plasma for the antibody screen. A newborn's ABO group is assigned solely on the testing of the patient's RBCs for the A and B antigens (forward typing) because the isohemagglutinins anti-A and anti-B are not present in the serum at birth. The use of cord blood specimens for infant blood type determination is discouraged because of possible contamination with Wharton's jelly and because of concerns about proper identification of the specimen.

If the newborn's antibody screen is negative, ABO- and Rh-specific RBCs may be transfused, and the antibody screen does not need to be repeated during the infant's hospitalization during the first 4 months of life. If the screening identifies passively acquired maternal blood group antibodies, as in Rh hemolytic disease of the newborn, O-negative RBCs should be transfused until repeat testing is negative for antibodies reacting against the ABO- or Rh-specific units. When antibodies to other RBC antigens other than D are detected, blood should be selected that is ABO and Rh specific but negative for the identified antibody. In cases in which reconstituted whole blood is needed for large-volume transfusion procedures (i.e., exchange transfusions, cardiopulmonary bypass, extracorporeal membrane oxygenation [ECMO]), the neonate may be given plasma that is ABO compatible with the neonate's RBCs, but receive RBCs that are compatible with maternal serum. This may mean that the ABO group of the RBC and FFP units are different. An alternative used by some transfusion centers entails the use of low isohemagglutinin titer, group-O whole blood, if available.[11] Infants whose Rh-negative mothers were treated with Rh immune globulin (RhIG) during pregnancy often have a positive DAT, owing to circulating anti-D antibody from the RhIG. The clinician must distinguish this situation from Rh hemolytic disease of the newborn.

In infants older than 4 months, repeat testing for blood group, Rh type, and antibody screening is performed within 72 hours of each RBC transfusion if the patient has received a transfusion during the past 3 months, or if the history is uncertain or unavailable.[46] Reverse ABO blood group testing, which detects anti-A and anti-B antibodies, is frequently deferred for the first 6 months of life because this testing is often weak or nonreactive in babies less than 1 year of age.

RED BLOOD CELL PREPARATIONS

RBC viability and functional activity require that RBCs be preserved in additive solutions that support their metabolic demands. All anticoagulant-preservative (AP) solutions contain citrate, phosphate, and dextrose (CPD), which function as an anticoagulant, a buffer, and a source of RBC metabolic energy, respectively. The addition of mannitol and adenine to existing additive solutions has increased the shelf life of RBCs from 21 days (CPD) to 35 days (CPDA-1) and to 42 days for newer AP solutions (Adsol, Optisol, Nutricell) by stabilizing the RBC membrane and maintaining 2.3-diphosphoglycenate and adenosine triphosphate within erythrocytes. Studies have shown that extended-storage preservative solutions are safe and as efficacious as CPDA-1 RBCs in increasing the hematocrit for neonates receiving small-volume (10 to 15 mL/kg) RBC transfusions.[23,57] However, no clinical studies have confirmed or refuted the effect of an AP on metabolic abnormalities in massive transfusion for the neonate. Therefore, many experts recommend avoiding RBCs stored in extended-storage media (Adsol, Optisol, Nutricell) for large-volume transfusions until such data have been published.

The highest relative blood volumes (in mL/kg) are found in neonates. Adult blood volumes on a per kilogram basis are achieved by 3 months of age (Table 46-24). A typical replacement transfusion is 10 to 15 mL of RBCs per kilogram. Because infants are so small, many pediatric transfusion centers dispense small aliquots from one RBC unit (300 to 350 mL) to one or several neonates who require multiple transfusions in order to decrease donor exposure and to conserve RBC inventory. This practice requires sterile connecting devices to ensure that the original RBC unit remains a closed system, and transfer packs or syringe sets that permit multiple aliquots to be removed. Studies have shown that CPDA-1 and AS-3 preserved split RBC packs effectively limit donor exposures and are safe for use in neonatal small-volume transfusions after 35 days of storage.[37]

TABLE 46–24 Estimated Blood Volumes

Age	Blood Volume (mL/kg)
Premature infant	90-105
Term newborn	82-86
1-7 days	78-86
1-12 months	72-78

From Price DC, et al: In Handmaker H, et al, editors: *Nuclear medicine in clinical pediatrics*, New York, 1975, Society of Nuclear Medicine, p 279.

Because RBC units are stored at 4° to 6°C, hypothermia can develop after massive transfusion unless the blood products are first warmed to body temperature. Inline blood warmers should be used for all RBC exchange transfusions, and radiant heaters should be avoided because they can result in hemolysis of the RBC component. When phototherapy is in progress, the blood component and tubing should be positioned to minimize exposure to phototherapy light, which may also cause hemolysis.[24]

Platelet Transfusion

INDICATIONS

As with older children and adults, platelet transfusions are administered to neonates therapeutically or prophylactically to prevent the hemorrhagic complications of thrombocytopenia. Neonates have different risks for bleeding given the same degree of thrombocytopenia. For example, thrombocytopenic neonates with neonatal alloimmune thrombocytopenia have a high risk for major bleeding, whereas those with sepsis or necrotizing enterocolitis and those with intrauterine growth restriction have an intermediate and low risk for major hemorrhage, respectively. Differences in platelet function or concurrent coagulopathy are likely causes for these discrepancies. The only randomized, controlled trial addressing whether platelet transfusions reduce major bleeding in neonates found no benefit of maintaining a normal platelet count (platelets >150,000/μL) in preterm neonates compared with those maintained at >50,000/μL. However, this study did not address bleeding risk or transfusion benefit for neonates with platelet counts below 50,000/μL.[7]

A number of platelet transfusion guidelines for the newborn have been proposed; however, given the lack of clinical trials addressing absolute bleeding risk in thrombocytopenia caused by different etiologies, they are based on expert panel recommendations garnered from clinical experience. Furthermore, because of the concern for intraventricular hemorrhage in the sick neonate, many physicians have traditionally adopted a fairly aggressive platelet threshold for transfusion. Murray and colleagues retrospectively studied 53 neonates (44 preterm) with severe thrombocytopenia and concluded that a threshold of 30,000/μL without other risk factors, or previous intraventricular hemorrhage, is safe for most neonates.[39] Thus, a generally accepted transfusion trigger for a platelet count of less than 30,000/μL has been endorsed for neonates without other risk factors, whereas some experts propose a higher trigger (<50,000/μL) for neonates with extremely low birthweight within the first week of life, clinically unstable neonates, and neonates with neonatal alloimmune thrombocytopenia (using HPA-compatible platelet products).[24a,49] Platelet transfusions are also indicated to treat hemorrhage associated with acquired (i.e., ECMO, cardiopulmonary bypass, uremia) or congenital qualitative platelet abnormalities (i.e., Glanzmann thrombasthenia, Bernard-Soulier syndrome), even if the platelet count is within the normal range.

PRETRANSFUSION TESTING

Platelets express intrinsic ABO antigens, but not Rh antigens. They should be ABO-group specific whenever possible, owing to reports of intravascular hemolysis following transfusion of ABO-incompatible platelets in infants and children.[8] Platelets do not routinely require crossmatching. If ABO-incompatible platelets must be used, plasma removal through volume reduction or washing or by selecting low isohemagglutinin (anti-A, anti-B) titer units are options. Routine volume reduction methods for all neonates should be avoided because about 20% of platelets are lost in the final product, which is resuspended in either saline or compatible plasma. Although Rh matching does not affect post-transfusion platelet survival, RBCs are present in small amounts of whole blood-derived platelet concentrate and can cause Rh sensitization in an Rh-negative recipient. A unit of whole blood derived platelets contains approximately 0.2-0.3 mL RBCs. Administration of RhIG should be strongly considered for any Rh-negative neonate, especially girls, within 72 hours of exposure to Rh-positive RBCs through a platelet transfusion. The recommended dose is 120 IU RhIG per 1 mL of RBCs transfused, administered intramuscularly (90 IU RhIG per 1 mL of RBCs intravenously).[26] When aliquots of apheresis platelets, which are relatively RBC free, are used, there should be limited to no concern for Rh sensitization.

COMPONENT DEFINITION

A standard unit of platelets, prepared from a single donation of whole blood, contains at least 5.5×10^{10} platelets in 50 to 70 mL of plasma. Apheresis platelets, often called single-donor platelets, contain a minimum of 3×10^{11} platelets in about 250 mL (range, 200 to 400 mL) of plasma, the equivalent of an estimated 6 units of whole blood-derived platelets. Single-donor platelets are split for neonatal use and offer the advantage of avoiding multiple donor exposures. Platelets are optimally stored at 20° to 24°C under constant agitation and have a shelf life of 5 days after collection. Transfusion of 10 to 15 mL/kg of platelets for neonates, or 0.1 to 0.2 unit/kg for children over 10 kg, should yield a platelet increment of 50,000/μL to 100,000/μL if no predisposing risk factors for refractoriness exist. It is important to account for device-related dead space (10 to 30 mL) when issuing the product because this can be considerable in relation to the overall platelet dose. The expected rise in the platelet count after transfusion may not be met because of destructive thrombocytopenia such as occurs with splenomegaly, fever, sepsis, disseminated intravascular coagulation, bleeding, or antibiotic therapy. Immune-mediated causes of platelet refractoriness, such as alloantibodies to platelet specific antigens (i.e. HPA-1a, 5b) in neonatal autoimmune thrombocytopenia, and autoantibodies to common platelet antigens in idiopathic thrombocytopenic purpura, require consideration in this population, so that appropriate management can be initiated.[11]

Granulocyte Transfusion

Neonates, particularly those with very low birthweight, are susceptible to overwhelming bacterial infection. Many factors contribute to this risk, including disruption of mucosal barriers, hypogammaglobulinemia, and qualitative neutrophil defects. Furthermore, preterm neonates may become neutropenic during sepsis, owing to a reduced capacity to increase myeloid progenitor cell proliferation with infections. Transfusion of granulocytes has been employed in the treatment of neonatal sepsis; however, the efficacy of such transfusions is controversial. Meta-analysis of the safety and efficacy of granulocyte infusion adjunctive to antimicrobial therapy in the treatment of septic neutropenic neonates failed to show that granulocyte infusions reduce morbidity or mortality.[38] However, granulocyte transfusion may be considered in neonates with qualitative neutrophil defects with severe (or progressive) bacterial or fungal infection, who have not responded to appropriate aggressive antimicrobial treatment.[51]

Granulocyte concentrates for neonatal transfusion are prepared by automated leukapheresis of healthy stimulated (dexamethasone with or without granulocyte colony-stimulating factor) donors and contain 1 to 2 × 10^9 neutrophils per kilogram in a volume of 10 to 15 mL/kg. Treatment should be continued daily until clinical improvement or neutrophil count recovery (absolute neutrophil count $>3000/\mu L$ in first week of life; $>1500/\mu L$ thereafter). All granulocytes should be gamma-irradiated and CMV negative because leukodepletion is contraindicated. Because granulocyte concentrates have a significant amount of RBCs (Hct, 15% to 20%), the component must be ABO, Rh, and crossmatch compatible with the intended neonatal recipient. Because granulocytes must be transfused within 24 hours of collection, U.S. Food and Drug Administration–mandated testing for blood products will not be completed before the product is released for administration, and therefore the risks and benefits of transfusing an untested blood product must be weighed by the medical team and the parents of the infant.[11]

There are unique risks to granulocyte transfusion. They include varying degrees of pulmonary reactions, from mild transient respiratory distress to severe pulmonary edema, hypoxia, and acute respiratory distress syndrome, and a high incidence of febrile transfusion reactions. Pulmonary complications have been reported in 4% of transfused infants,[38] and severe pulmonary reactions resembling TRALI have been reported.[40] Mild to moderate reactions occur in 25% to 50% and severe reactions in about 1% of all granulocyte transfusions. Administration of amphotericin B treatment should be not given within 6 hours of granulocytes owing to suspected increased risk for severe pulmonary reactions.

Although granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor have been used successfully to stimulate neutrophil numbers, and intravenous immune globulin has been attempted to augment traditional antimicrobial therapy to support septic neonates, data on efficacy are inconclusive.[14,53] Because of the lack of clear consensus on their impact on improving host defense mechanisms and improving outcomes, these adjuncts to standard antimicrobial and antifungal therapy need further investigation.

Fresh-Frozen Plasma Transfusion

Plasma can be prepared by either whole blood separation or by apheresis. When the plasma product is frozen to −18°C or colder within 8 hours of collection, it is labeled as FFP (about 250 to 300 mL) and can be stored at this temperature for up to 1 year.[11] To conserve plasma inventory and limit donor exposures for infants who receive only fractions of an FFP unit, plasma can be separated into a system of multiple satellite bags and frozen as aliquots. Once thawed, FFP can be further subdivided into aliquots for multiple neonates by sterile connecting devices, stored at 1° to 6°C for up to 5 days and transfused as *thawed plasma*.[24] Although thawed plasma has about 40% factor V and VIII (heat labile factors) activity, effective hemostasis is maintained at this level, making thawed plasma clinically similar to FFP.

FFP is used primarily to treat acquired coagulation factor deficiencies as a result of disseminated intravascular coagulation, liver failure, vitamin K deficiency from malabsorption, biliary disease or warfarin therapy, or dilutional coagulopathy from massive transfusion. It can also be used for specific factor replacement in congenital factor deficiencies (e.g., factor X, factor XI, protein C, protein S, antithrombin) when specific factor concentrates or recombinant products are not manufactured or unavailable.[11,24,46] FFP is not indicated for volume expansion, for enhancement of wound healing, or as first-line treatment for congenital factor deficiencies when either a virally inactivated plasma-derived factor concentrate or recombinant factor is available.

Plasma transfusions should be ABO compatible with the neonate's RBCs to avoid passive transfer of isohemagglutinins from ABO-incompatible plasma resulting in hemolysis.[24] Because the freezing process renders the frozen-thawed plasma component free of viable leukocytes, FFP is not screened for CMV antibody, nor are leukoreduction and irradiation necessary for the prevention of CMV reactivation and TA-GVHD, respectively. However, passive administration of antibody to CMV in FFP may cause CMV IgG testing to become positive in the transfused neonate. This does not represent CMV infection, and the antibody disappears in a time course consistent with the 21-day half-life of γ-globulin.[50]

FFP is typically dosed at 10 to 15 mL/kg. Assuming that 1 mL of FFP generally equates to 1 mL of factor activity, one can predict the amount of replacement of most factors after plasma transfusion. For example, for a *preterm* infant, the calculations are as follows:

1. 1 mL of factor activity = 1 mL FFP
2. Total blood volume (TBV) = Weight (kg) × 100 mL/kg
3. Total plasma volume (TPV) = TBV × (1 − Hct)
4. Unit of factor needed = TPV × (desired factor [%] − initial factor [%])

Example: 1 kg preterm infant, with Hct: 55%; the desired increment in a given factor of 30%:

$$\begin{gathered}\text{TBV} = 100\text{ mL, and TPV} = 45\text{ mL}\\ \text{Units of Factor needed} = 45 \times (0.30) = 15\text{ mL}\\ \text{Amount of FFP needed} = 15\text{ mL (or 15 mL/kg)}\end{gathered}$$

Using these calculations for a *preterm* infant, it is evident that 10 to 15 mL/kg of FFP will replace about 10% to 30% of most factors immediately after transfusion. It is important for the clinician to know the half-lives of the factors because factor half-lives vary. Furthermore, vitamin K-dependent factors are lower in neonates, thereby prolonging both the prothrombin time and activated partial thromboplastin time. Correlation of laboratory values to clinical status of the individual is therefore important when devising an FFP dosing schedule for a coagulopathic infant. It is critical that appropriately collected specimens for evaluation of coagulation factors be obtained in advance of FFP transfusion.

Cryoprecipitate Transfusion

Cryoprecipitate is the cold-insoluble precipitate prepared from FFP that has been thawed slowly at 1° to 6°C, the supernatant removed, and refrozen at −18°C. Each unit (bag) of cryoprecipitate is derived from a single whole blood donation and has a shelf life of up to 1 year. A unit (10 to 15 mL) of cryoprecipitate contains a minimum of 80 U of factor VIII activity and 150 mg of fibrinogen. There are no standards for the quantity of the other factors; however, there is about the same amount of von Willebrand factor and factor XIII in one unit as 10 to 15 mL/kg of FFP.[46] Therefore, it is a useful product in infants who require higher concentrations of factors VIII, XIII, von Willebrand factor, or fibrinogen levels, and who are volume restricted. Cryoprecipitate is indicated in the treatment of bleeding episodes associated with von Willebrand disease or hemophilia A only when U.S. Food and Drug Administration–licensed recombinant factor concentrates and viral inactivated pooled plasma-derived factor concentrates are not available. Cryoprecipitate is the treatment of choice for factor XIII deficiency, congenital afibrinogenemia, dysfibrinogenemia, and severe hypofibrinogenemia (<150 mg/dL) associated with bleeding.[11,50] In general, an infant should receive 1 unit of cryoprecipitate per 5 kg, which increases the total fibrinogen by about 100 mg/dL.

SPECIAL TOPICS IN NEONATAL TRANSFUSION

Exchange Transfusion

Exchange transfusion is the replacement of most or all of the recipient's RBC mass and plasma with appropriately compatible RBCs and plasma from one or more donors. The amount of blood exchanged generally is expressed in relation to the recipient's blood volume (e.g., as a single- or double-volume exchange, or a partial exchange).

INDICATIONS

Neonatal exchange transfusions are most commonly used in infants with hemolytic disease of the newborn. Double-volume exchange transfusions also are frequently used in newborns with severe jaundice from other causes to prevent kernicterus and other toxicity related to hyperbilirubinemia.[24] Bilirubin levels warranting exchange transfusion are discussed in Chapter 48. Meta-analysis has shown that intravenous immune globulin administration (0.5 to 1 g/kg) can result in significant reduction in the incidence of exchange transfusion for term infants with hemolytic disease of the newborn. Therefore, intravenous immune globulin should be considered early when serum bilirubin levels continue to rise despite aggressive phototherapy or when the bilirubin level is within 2 to 3 mg/dL of the exchange level.[3,6] Exchange transfusions can also be used, albeit infrequently, to remove exogenous (drugs) or endogenous (metabolic) toxins.

The efficiency of exchange transfusion diminishes exponentially as the procedure continues. The kinetics of exchange are very similar, regardless of whether a continuous technique (simultaneous withdrawal and replacement) or discontinuous technique (alternating withdrawal and replacement) is used. The effectiveness of exchange transfusion varies with the component being removed. The efficiency is highest for RBC exchange. A double-volume exchange transfusion results in removal of about 85% of the neonate's RBCs; however, the amount of bilirubin or maternal alloantibody removed by exchange transfusion is significantly less (25% to 45%) because of an equilibrium between the intravascular pool and the extravascular tissues for bilirubin, antibody, and similar substances.

The optimal volume for an exchange transfusion is twice the infant's blood volume.[48] Little is gained by exceeding two blood volumes. When anticipating the volume needed for double-volume exchange, the total volume required depends on the whether the infant is preterm. For example, using 2 × total blood volume (TBV):

- 2-volume exchange volume (preterm) = 100 mL/kg × 2, or 200 mL/kg
- 2-volume exchange volume (term) = 85 mL/kg × 2, or 170 mL/kg

To perform the exchange transfusion, aliquots of the reconstituted whole blood product are administered while equal amounts of the infant's blood are withdrawn, with careful attention not to exceed 5 mL/kg or 5% of TBV at a time (over 2 to 10 minutes).

CHOICE OF BLOOD COMPONENTS

Either stored whole blood if available or reconstituted whole blood (i.e., RBCs plus FFP) can be used for neonatal exchange transfusions. The RBC component should be group-O negative or ABO and Rh compatible to maternal serum for Rh hemolytic disease of the newborn. Fresh (<5 to 7 days) CPDA units should be used because the safety of extended storage media has not been amply studied for neonatal large volume transfusions. If only older CPDA units or extended storage units are available, the RBC units can be washed or the supernatant removed. The RBCs are reconstituted with AB or compatible plasma to a final hematocrit of 40% to 50%. Furthermore, components should be CMV risk reduced (leukodepletion), gamma-irradiated, and sickle negative. Both whole blood and reconstituted whole blood are deficient in platelets. Platelets are not added to reconstituted blood during an exchange because this could lead to increased microaggregate formation. Infants who are significantly thrombocytopenic (platelet count <30,000/μL) after an exchange transfusion or who are bleeding should receive platelet transfusion. For infants with hemolytic disease of the newborn caused by other RBC antibodies, the RBC product should be specifically selected to be negative for the offending antibodies.

Potential complications of exchange transfusion include hypocalcemia, hyperglycemia (with subsequent rebound hypoglycemia), dilutional thrombocytopenia, neutropenia, umbilical vein and arterial thrombosis, necrotizing enterocolitis, intracranial pressure fluctuations resulting in intraventricular hemorrhage, air embolization, and infection.[48] In a retrospective review of 55 neonates undergoing 66 exchange transfusions, most adverse events associated with exchange transfusions were asymptomatic laboratory abnormalities, with thrombocytopenia (44%), hypocalcemia (29%), and metabolic acidosis (24%), the most common abnormalities needing treatment. Adverse events were more frequent in exchanges done on preterm infants born before 32 weeks, in infants with other significant comorbidities, and when umbilical catheters were used compared with other methods of central venous access.[44]

Partial Exchange Transfusion

About 5% of all neonates are born with or develop polycythemia. Infants of diabetic mothers and neonates who are small for gestational age are at higher risk. Neonatal polycythemia is defined as a venous hematocrit greater than 65% within the first week of life. Partial exchange transfusion effectively lowers the hematocrit and reduces whole blood viscosity in polycythemic neonates who have hyperviscosity. Partial exchange transfusion is also useful for correcting severe anemia without the risk for fluid overload and heart failure.

The long-term benefit of early partial exchange transfusion in polycythemic neonates is controversial, at least partly because the prognosis for such infants depends greatly on the etiology. An hematocrit greater than 65% is generally used as the stimulus for exchange transfusion because as the hematocrit rises over this level, blood viscosity significantly increases, and oxygen transport diminishes.

A partial exchange is used to normalize the hematocrit to below 60% by removing infant whole blood and replacing with equal volume of isotonic crystalloid solution. Crystalloid solutions are preferable to plasma to decrease exposure to plasma and because necrotizing enterocolitis has been associated with the use of plasma as replacement solution. The volume of exchange required can be calculated with the following formula:

$$\begin{aligned}\text{Volume of exchange (mL)} &\\ &= \text{total blood volume (mL)}\\ &\quad\times\left[\frac{\text{observed Hct} - \text{desired Hct}}{\text{observed Hct}}\right]\end{aligned}$$

Example: 1-kg preterm infant with Hct 68%, desired post-partial exchange Hct 55%

$$\begin{aligned}\text{Volume of exchange (mL)} &\\ &= 100\text{ mL}\times\left[68-\frac{55}{68}\right]\\ &= \text{about 20 mL of crystalloid}\\ &\quad\ \text{exchanged with whole blood}\end{aligned}$$

To correct severe anemia, packed RBCs are used as the replacement fluid for the whole blood withdrawn. The formula used to calculate the volume required for exchange is similar to the one above; however, the hematocrit of the RBC product used must be taken into account. RBCs in CPDA-1 usually have a hematocrit of approximately 70%; thus the formula is:

$$\begin{aligned}\text{Volume of exchange (mL)} &\\ &= \text{TBV (mL)}\times\left[\frac{\text{Desired Hct} - \text{Observed Hct}}{\text{Hct of unit} - \text{Observed Hct}}\right]\end{aligned}$$

Example: 1-kg preterm infant with Hct 21%, desired post-partial exchange Hct 45%

$$\begin{aligned}\text{Volume of exchange (mL)} &\\ &= 100\text{ mL}\times\left[\frac{45-21}{70-21}\right]\\ &= \text{49 mL of CPDA RBCs}\\ &\quad\ \text{exchanged with whole blood}\end{aligned}$$

If RBCs preserved in other solutions are used, the equation must be altered to take into account the average hematocrit of the product. The technique of partial exchange transfusion is similar to that used in larger-volume exchange. A discontinuous methodology is most often used; aliquots of 5 mL/kg or less should be used for each withdrawal and infusion.

Extracorporeal Membrane Oxygenation

See also Chapter 44, Part 8.

Because of the large volume of transfused RBCs used for ECMO, RBCs used in the bypass circuit should be less than 7 to 14 days old to avoid high potassium levels in older blood.[34] In the infant with presumed or suspected cellular immunodeficiency, the blood products should undergo CMV risk reduction (CMV seronegative *or* leukoreduced) and gamma irradiation. Although there is mounting anecdotal evidence that RBCs preserved in extended storage media (AS-1, AS-3) are safe for ECMO, most ECMO centers use RBC products stored in CPD or CPDA preservatives or reduce the additive before use.[24] Hemolysis from mechanical damage and phlebotomy contributes to ongoing RBC transfusion requirements. Thrombocytopenia occurs in all patients undergoing ECMO as a result of accelerated platelet destruction. This, coupled with the need for systemic anticoagulation with heparin to prevent clotting within the extracorporeal circuit (see Part 1 of this chapter), places infants on ECMO at significant risk for hemorrhage. Platelets should be maintained at greater than 50,000 to 150,000/μL or higher in infants undergoing major surgery like diaphragmatic hernia repair while on ECMO. Activated clotting times are used to measure coagulation parameters, and FFP and cryoprecipitate are often needed to maintain normal clotting factors.

CHAPTER 47

The Gastrointestinal Tract

PART 1

Development and Basic Physiology of the Neonatal Gastrointestinal Tract

David K. Magnuson, Robert L. Parry, and Walter J. Chwals

The human gastrointestinal (GI) tract is a complex combination of organs whose primary function is to digest and absorb nutrients. Many important secondary functions are also performed, such as the endocrine function of the pancreas. In fact, what was once considered a simple system of digestion and absorption is now recognized as something much more complex and dynamic. Furthermore, as with the respiratory system, in order to perform its duties, the GI tract must be in continuity with the environment. This places the additional demand of having mechanisms in place to protect the host from toxins and pathogens. It is remarkable that this tube, open to the outside world at both ends and colonized by bacteria for a significant portion of its length, is tolerated so well and has relatively few complications associated with it. But troubles do occur, and in the neonate, most can be traced to developmental anomalies.

THE BEGINNING

During gestation, the alimentary canal can be simply considered as the folding of endoderm and splanchnic mesoderm into a tube at the end of week 3 and the beginning of week 4.[6] As the head fold forms, the cranial part of the yolk sac becomes enclosed within the embryo and becomes the foregut. Shortly thereafter, the caudal portion of the yolk sac becomes enclosed and forms the hindgut. The midgut resides between the foregut and the hindgut, near the yolk sac, which remains outside the embryo. The midgut remains in communication with the yolk sac until the yolk stalk closes during the 10th week of gestation. Initially, the digestive tube ends blindly—cranially at the oropharyngeal membrane and caudally at the cloacal membrane. These membranes, made up of endoderm and ectoderm, break down, with the oropharyngeal going first at the start of week 4 followed by the cloacal at the start of week 6.

ESOPHAGUS

The esophagus is the only portion of the GI tract that has neither digestive nor absorptive function. Rather, it serves as a conduit between mouth and stomach and, at the gastroesophageal junction, functions to avoid reflux of stomach contents back up the esophagus. Although this task sounds simple, the esophagus performs its roles so well that no esophageal replacement has been found that does anywhere near as good a job. All efforts are made to keep a native esophagus, even a severely compromised one, rather than go with any replacement.

The fully developed esophagus extends from the pharynx and cricopharyngeal sphincter in the neck to the lower esophageal sphincter and gastroesophageal junction in the abdomen. The blood supply to the esophagus is segmental. The upper esophagus is supplied by branches descending from the inferior thyroid artery. The middle and lower thirds of the esophagus are supplied by branches arising directly from the bronchial vessels or the descending thoracic aorta. The abdominal and lower esophagus also receive blood supply from the left gastric and inferior phrenic arteries. The esophagus varies in length from 13 to 25 cm depending on the age and height of the patient. There are four areas of natural anatomic constriction of the esophagus: (1) at the level of the cricopharyngeal sphincter, (2) as the aortic arch crosses anteriorly, (3) as the left main stem bronchus crosses anteriorly, and (4) at the level of the lower esophageal sphincter. Foreign bodies in the esophagus tend to lodge at one of these areas of constriction, and burns from caustic ingestion tend to be more severe in these regions.

The esophagus is differentiated from the primitive foregut during the 4th week of gestation.[7,9] A tracheoesophageal septum is evident at this time initiating the division of the trachea anteriorly from the foregut posteriorly. The septum remains at about the same level in the fetus while the body grows cranially. This leads to elongation of the esophagus, primarily from "ascent" of the pharynx rather than "descent" of the stomach. It reaches its full length, relative to the size of the developing fetus, during the 7th week of gestation. Aberrations during this phase of development result in esophageal atresia and tracheoesophageal fistulas.

The lumen of the esophagus is nearly obliterated during the 7th and 8th weeks of gestation, secondary to rapid proliferation of mucosal epithelial cells. Temporary obliteration of the lumen (as in the duodenum) is thought not to occur.

A single lumen is clearly present by the 10th week, with growth of the muscular wall.

The muscular wall of the esophagus is similar to that of the rest of the GI tract, with an outer longitudinal layer and a circular inner layer. The more highly developed longitudinal layer forms during the 9th week of gestation, whereas the circular layer forms during the 6th week. There is no serosa on the esophagus except in the short abdominal portion.

The epithelial lining of the esophagus is derived from the primitive endoderm. At the 10th week of gestation, this is ciliated, but a stratified, nonkeratinizing, squamous epithelium begins replacing the ciliated epithelium at about the 4th month of gestation. Some ciliated epithelium along the length of the esophagus may persist until birth. The striated muscle of the upper third arises from mesoderm of the branchial arches, whereas the smooth muscle of the distal two thirds is derived from splanchnic mesenchyme. Therefore, diseases of smooth muscle tend to affect the lower esophagus only.

Small glands of mucus- and bicarbonate-secreting cells with ducts opening onto the surface of the epithelium are scattered throughout the length of the esophagus, particularly in the lower third.

By 8 weeks' gestation, immature neurons are identifiable within the wall of the esophagus. These nerves are derived from both parasympathetic and sympathetic fibers. The cervical sympathetic trunks send fibers along the inferior thyroid artery to the upper third of the esophagus, whereas the middle and lower thirds are supplied by branches from the greater splanchnic nerves. The thoracic esophagus is supplied by branches of the esophageal vagal plexus, arising directly from the vagus trunks in the chest.

The act of swallowing is initiated by impulses from the swallowing center, an area in the reticular formation of the rostral medulla where the nuclei of cranial nerves IX and X are located. The initial event in esophageal peristalsis is stimulation of the longitudinal muscle layer, which is followed by the segmental activation of the circular muscle and relaxation of the lower esophageal sphincter. The peristaltic wave begins in the pharynx and continues through to the gastroesophageal junction without interruption. Whereas primary waves are initiated from the swallowing center, secondary peristalsis is mediated by local intramural pathways to return refluxed material in the lower esophagus to the stomach.

The upper esophageal sphincter corresponds to the cricopharyngeal muscle. There is no morphologic distinction in the muscular wall of the lower esophagus that would identify this sphincter, although clearly one functionally exists. The primary role of this sphincter is to prevent the reflux of gastric contents back into the lower esophagus. The lower esophageal sphincter relaxes as the primary peristaltic wave traverses the esophageal body, and it remains open until the peristaltic wave enters the sphincter and closes it. Disordered lower esophageal sphincter function is thought to be the primary mechanism for gastroesophageal reflux.

STOMACH

The stomach first appears as a fusiform dilation of the caudal part of the foregut at the end of the 4th week of gestation.[5] At this time, the stomach is suspended between the posterior and anterior body walls by a ventral and dorsal mesentery. During weeks 6 through 10, the stomach undergoes rotation in two planes, as well as growth differentials that lead to the appropriate size and orientation of the organ as seen at birth. One rotation is 90 degrees counterclockwise (viewed from below upward) along the longitudinal axis of the stomach. This brings the dorsal aspect of the stomach toward the fetus' left side, and the ventral aspect now points to the right. The two mesenteries follow this rotation, with the ventral mesentery finally extending horizontally from the stomach to the liver as the lesser omentum. The cranial portion of the dorsal mesentery runs horizontally to the spleen laterally as the gastrosplenic ligament, and it contains the short gastric vessels. A second, lesser rotation, in conjunction with a growth differential favoring greater growth on the dorsal (now left lateral) side of the stomach, leads to the organ's final position. This rotation is clockwise around the body's anterior-posterior axis when viewed from the front and brings part of the now left lateral (formerly dorsal) side of the stomach to point caudally. This part of the stomach still has the caudal portion of the stomach's dorsal mesentery attached, which now grows quite quickly caudally forming a two-layer fat pad that covers the bowel and extends to the pelvis. The two fat layers fuse to each other and to the colon and become the greater omentum. The space now created behind the stomach is called the lesser sac. It has one entrance, the epiploic foramen (foramen of Winslow), located beneath the free edge of the ventral mesentery that now extends from the area of the gastroduodenal junction to the liver.

The final shape of the stomach along with the various epithelial cell types that constitute its mucosal lining create distinct areas: the cardia around the gastroesophageal (GE) junction; the fundus, which projects cephalad from the gastroesophageal junction, the body, which is the vast majority of the gastric reservoir; and the antrum, the portion of the stomach immediately before the pylorus. There are three muscle layers of the stomach: the outer longitudinal, the intermediate circular, and the inner oblique. The three layers permit complex mixing and churning movements that help begin the process of digestion.

The blood supply to the stomach is extremely rich and is derived principally from the celiac axis. Four major vessels are felt to provide the stomach with blood: the right and left gastric and the right and left gastroepiploic. Also important are the short gastric arteries off the splenic artery. Venous drainage is via the portal system, with the exception of the gastroesophageal junction which can drain to the systemic system via esophageal veins (critical to the development of esophageal varices). The blood supply to the stomach is so redundant that the organ can survive if three of the four major arteries are divided.

The gastric epithelium is made up of a diverse cell population distributed in a regionally specific manner. The early gastric mucosa is initially a stratified or pseudostratified columnar epithelium that later becomes cuboidal. This mucus-secreting cuboidal epithelium then becomes peppered with gastric pits that are first observed between gestational weeks 6 and 9. By 20 weeks, the mucosa of the stomach is mature in appearance. At the base of the gastric pits are the gastric glands, which contain the effector and regulator cells of gastric secretion.

The different cell populations of the gastric glands in various regions of the stomach allow the stomach to be histologically and functionally compartmentalized. Parietal cells are found predominantly in the gastric fundus and body and less often in the proximal antrum and can be identified in gastric glands as early as week 10. They produce both hydrochloric acid and intrinsic factor under complicated regulatory control. Chief cells are found principally in the gastric fundus and body; first appearing in gestational week 12. They are located exclusively at the base of the gastric glands, where they synthesize, store, and secrete pepsinogen. Pepsinogen is hydrolyzed to the active proteolytic enzyme pepsin in the acid environment of the stomach.

Enteroendocrine cells are present throughout the stomach, duodenum, and distal intestine. Because of their ability to produce biologically active amines and peptides and to internalize certain precursor molecules, they are referred to as *amine precursor uptake and decarboxylation* (APUD) cells. There are many distinct types of enteroendocrine and neuroendocrine cells found in the gastric mucosa. These cells are among the first to populate the gastric glands, appearing at 8 to 9 weeks. The most common and well-characterized are the G cells, which produce gastrin, and the D cells, which produce somatostatin and amylin. These cells predominate in the gastric antrum. Other enteroendocrine cells are ubiquitous both within the gastric glands and within the duodenal wall. They are responsible for producing such diverse amines and peptides as histamine (from the enterochromaffin-like cells), serotonin, dopamine, vasoactive intestinal peptide (VIP), glucagon, gastric-releasing peptide (GRP), motilin, and ghrelin. Interestingly, the A cells, which produce glucagon, are present only in fetal and neonatal glands. Considered along with the trophic effect of many GI hormones, this suggests a growth and differentiation role for these substances, along with the digestive and regulatory roles they are currently known to have.

All three components of the autonomic nervous system—sympathetic, parasympathetic, and enteric—innervate the stomach. The parasympathetic and enteric predominate. Sympathetic innervation is predominantly inhibitory to GI function and primarily uses the postganglionic neurotransmitter norepinephrine.[3] The parasympathetic pathways mediated by acetylcholine are generally stimulatory. The enteric nervous system (ENS), on the other hand, uses a variety of neurotransmitters including dopamine, somatostatin, VIP, GRP, ghrelin, and cholecystokinin. The ENS is the largest and most complex compartment of the autonomic nervous system and comprises more than 10^8 resident neurons within the wall of the GI tract. The ENS is anatomically separate from the CNS (i.e., the sympathetic and parasympathetic systems).

Sympathetic innervation originates from cell bodies within the thoracic spinal cord and extends through presynaptic fibers in the greater splanchnic nerve to postsynaptic neurons in the celiac ganglion, whose axonal fibers follow blood vessels into the gastroduodenal wall. Parasympathetic presynaptic nerves originate in the brainstem and follow the vagus nerves to the stomach. ENS precursors differentiate from neuroblasts located in the vagal area of the neural crest and migrate with the vagus nerves to the developing GI tract. These ENS neurons then further differentiate, proliferate, and establish connections to each other, to other autonomic pathways, and to developing gastric secretory and muscle cells. There is significantly more ENS than CNS activity within the GI tract, suggesting a more powerful role for intrinsic (ENS) control than for extrinsic (CNS) control.

The stomach has two distinct functional zones based on motor activity differences. The proximal zone, which includes the fundus and the proximal third of the body of the stomach, serves as a reservoir in which an ingested meal is stored. Its ability to distend without increasing intraluminal pressure is important during bolus feeding. The proximal stomach generates slow, sustained tonic contractions under CNS control via the vagus. This action creates a constant pressure gradient that controls the passage of material through the stomach. Vagotomy significantly impairs this function, causing rapid emptying of fluids.

Motor activity in the stomach distal to the proximal third of the body of the stomach is characterized by spontaneous depolarizations that result in phasic, directional contractions. This gives this portion of the stomach the ability to mix and grind solid food and to empty mixed food particles into the duodenum in a controlled fashion. During the fasting state, gastric activity follows a 90- to 120-minute repetitive pattern called the interdigestive migrating motor complex. This four-phase complex runs from mechanically silent to coordinated contractions that empty the gastric lumen of all indigestible materials. The fed state occurs when the migrating motor complex is interrupted by the arrival of ingested food. Now, the stomach begins forceful, nonpropagated contractions in the distal stomach coupled with coordinated contractions of the pyloric sphincter that churn food into small particles. A gastric pacemaker located along the greater curvature at the proximal boundary of the distal zone triggers these contractions at a rate of three to four cycles per minute. When the average particle size reaches 1 mm, chyme is allowed to empty into the duodenum. Complex CNS and ENS coordination permits adequate breakdown of the food and ensures that the rate of gastric emptying is adjusted to provide an isocaloric flow of nutrients into the duodenum over time.

Gastric secretory function evolves early in development. By 10 weeks' gestation, parietal and enteroendocrine cells have begun to differentiate, and by 12 to 13 weeks, gastrin, hydrochloric acid, pepsin, and intrinsic factor (IF) can all be detected. Mucus and bicarbonate secretion commences later, at about the 16th week. The gastric luminal pH of full-term newborns is neutral, but it is as low as 3.5 within a few hours. By 48 hours, the pH is between 1.0 and 3.0. Premature infants have a prolonged period of alkalinity, often many days, that is related to the degree of prematurity.

The production and secretion of hydrochloric acid by gastric parietal cells is governed by complex neurocrine, endocrine, and paracrine pathways, with little evidence for a final common pathway. The parietal cell can receive input and respond to a large variety of inputs, making its regulation by medical and surgical treatments difficult. Gastric acid has many functions. One is to facilitate protein digestion, but the lack of malabsorption problems in patients with achlorhydria indicates that this role may not be critical. Normal acid secretion does, however, play an integral role in initiating the digestive process. Gastric acid also creates a barrier to the entrance of bacteria into the GI tract. This not only protects the upper aerodigestive tract but also insulates the bacteria downstream from constant challenges from above. This is consistent with recent data that acid suppression therapy for gastroesophageal reflux may be associated with a higher incidence of lower respiratory tract infections.[8]

DUODENUM, PANCREAS, AND BILIARY SYSTEM

The duodenum is the short retroperitoneal portion of the GI tract that connects the foregut to the midgut. At its proximal end, it connects to the outlet of the stomach, the pylorus, and it ends a short distance later at the ligament of Treitz, where the GI tract becomes an intraperitoneal organ once again and becomes the jejunum. Like the stomach, the duodenum undergoes a rotational process that brings it to its final C-loop configuration (Fig. 47-1). This 270-degree counterclockwise rotation swings the duodenum under the superior mesenteric artery. During this rotation, the duodenum's dorsal mesentery shortens, which allows the duodenum to become fixed in the retroperitoneal position across the upper abdomen from the pylorus (to the right of midline) to the ligament of Treitz (to the left of midline). This fixation is absolutely critical, because, from the ligament of Treitz to the cecum (the next retroperitoneal portion of the GI tract located in the right lower quadrant), the bowel is on a mesentery and free to float about the peritoneal cavity. The bowel thus becomes fixed within the peritoneal cavity at the two most widely separated points available—the ligament of Treitz in the left upper quadrant and the cecum in the right lower quadrant. Because the mesenteric base is therefore so broad, it is impossible for the floating, intraperitoneal bowel to twist on its mesentery, thus compromising its own blood supply. However, any failure of proper rotation and fixation of the bowel can lead to the twisting of the bowel on its mesentery (i.e., volvulus) and the subsequent catastrophe of interruption of the flow of blood to the bowel.

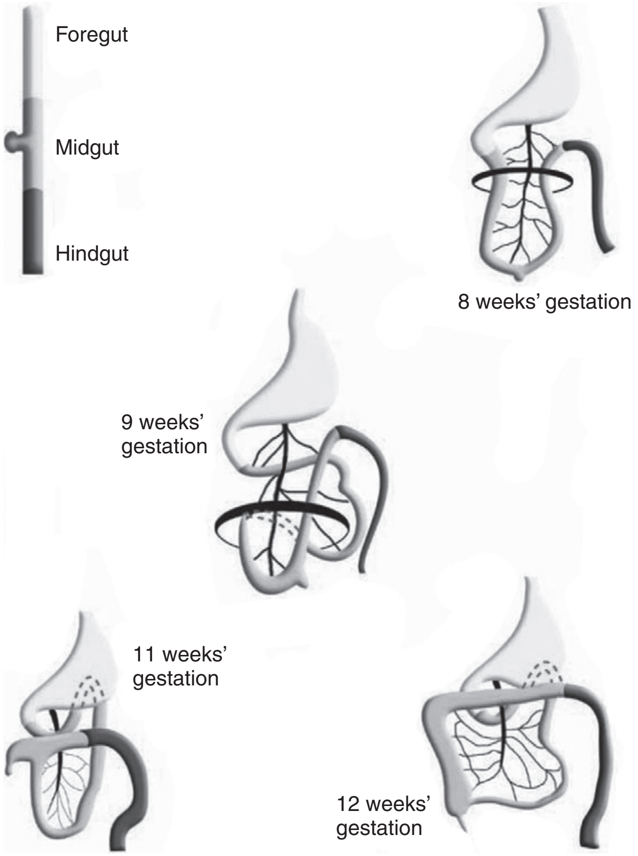

Figure 47–1. Normal rotation of the developing gut. Eight weeks' gestation: elongation of the midgut and superior mesenteric artery, herniating into the umbilical stalk. Nine and 11 weeks' gestation: 270-degree counterclockwise rotation of duodenal-jejunal segment and 270-degree counterclockwise rotation of ileo-colic segment. Twelve weeks' gestation: final orientation of the normally rotated gut.

The rotation of the bowel occurs during the 6th to 10th weeks of gestation. Concurrently, there is a rapid epithelial proliferation (along with the rectum and esophagus) that obliterates the hollow lumen and converts the duodenum to a solid, cordlike structure. Vacuoles then appear and gradual recanalization occurs. The distal duodenum does not appear to pass through a solid phase. Defects in this proliferation and recanalization process are believed to lead to the problems of duodenal atresia, web, and stenosis.

The duodenum is divided into four portions corresponding to the curvatures of the C loop. The blood supply is derived from the celiac axis through the superior pancreaticoduodenal branches of the gastroduodenal artery, and the superior mesenteric artery through the inferior pancreaticoduodenal branches. Consistent with the location of the original liver bud, this transition from celiac to superior mesenteric blood supply defines the transition from foregut to midgut. A consistent landmark in the medial portion of the duodenum, near the end of the foregut, is the ampulla of Vater, which represents the confluence of common bile duct and pancreatic ducts and their entry into the duodenum.

The liver and biliary system develop within a bud along the free edge of the ventral mesentery, with stomach and bowel rotation bringing them to their final location in the right upper quadrant.[1] Also within this bud is the primordial ventral pancreas. Opposite this ventral pancreatic bud (including liver and biliary primordium) is the dorsal pancreatic bud. During rotation, the ventral pancreatic bud fuses to the dorsal bud and becomes one organ. Failure of this rotation leads to the problem of annular pancreas. The biliary and pancreatic drainage systems also fuse during rotation, so that the common bile duct descends in the remnant free edge of ventral mesentery, along with the portal vein and hepatic artery, then passes behind the duodenum to join with the main pancreatic duct at the ampulla of Vater. This main pancreatic duct is formed from the confluence of the original ventral pancreatic duct with the distal dorsal pancreatic duct. The proximal dorsal pancreatic duct remains as the accessory pancreatic duct. The biliary and pancreatic ductal systems are complete by the 10th to 12th gestational week. With so many rotation and fusion requirements to produce the "classic" biliary-pancreatic ductal anatomy, it is no wonder that one sees the "classic" form less than 50% of the time. Blood supply to the gallbladder arises from the celiac artery. The pancreas is supplied by numerous branches of the celiac and superior mesenteric arteries.

The layers of the duodenum are the muscularis, the submucosa, and the mucosa. The muscularis is made up of smooth muscle cells, which are divided distinctly into two separate layers: an outer, longitudinal layer and an inner, circular layer. The submucosa is a band of dense connective tissue lying just under the mucosa. The mucosa is the innermost layer and is composed of three distinct layers: the muscularis mucosa, the lamina propria, and the epithelial cell lining. The most striking feature is the villi, 1.5 mm tall in the duodenum and decreasing in size through to the ileum. Crypts of Lieberkühn surround the base of each villus and average one-third to one-fourth the height of the villi.

Like the rest of the small bowel, the duodenal mucosa is made up mainly of enterocytes, tall columnar epithelial cells that are responsible for absorption (see Small Intestine later). The duodenum is also richly populated with enteroendocrine cells, along with goblet cells, Paneth cells, and lymphoid aggregates of Peyer patches. The enteroendocrine cells are stimulated by nutritional substrates delivered from the stomach, and they secrete mediators that regulate a variety of digestive processes. Secretin is produced by the duodenal S cells in response to luminal acid, stimulating bicarbonate secretion from the pancreas, liver, and duodenal Brunner glands and mucosal cells. Cholecystokinin, produced by duodenal I cells in response to certain fatty acids and amino acids, stimulates gallbladder contraction and pancreatic exocrine secretion.

The pancreas is a central metabolic organ with key roles in both exocrine and endocrine function.[4] It is the primary source of digestive enzymes: more than 20 different enzymes are synthesized and stored in the secretory acini. The proteolytic enzymes such as trypsin, chymotrypsin, and carboxypeptidase are secreted as inactive proenzymes. They are converted to active enzymes by enterokinase, an intestinal brush border enzyme, when they reach the duodenal lumen. These enzymes, in turn, can activate other proenzymes. Pancreatic amylase and lipase are secreted in their active form. The secretory acinar cells are under complex CNS, ENS, and hormonal regulation. The ducts that drain the acini are lined by cells that secrete water and bicarbonate. Secretin stimulates this fluid and bicarbonate secretion, which raises intestinal pH and thereby facilitates pancreatic enzyme activity.

The pancreas also has an essential role in the hormonal regulation of metabolism and glucose homeostasis. These endocrine functions are provided by the islets of Langerhans, which make up about 1% to 2% of the pancreatic mass. These 1 to 2 million islets are more plentiful on the pancreatic tail and are also under complex CNS, ENS, and hormonal control. There are four distinct cell types within the islets: alpha cells for glucagon production, beta cells for insulin, gamma cells for somatostatin, and PP cells for pancreatic polypeptide.

SMALL INTESTINE

The small intestine is the major digestive and absorptive portion of the GI tract. The gut initially herniates out of the fetus's abdominal domain and lengthens rapidly during the 6th to 12th weeks of gestation.[11] As described earlier (see Duodenum, Pancreas, and Biliary System), on reentry into the abdominal cavity, the small bowel undergoes a 270-degree twist around the superior mesenteric artery axis to bring it into its final anatomic position. This positioning is complete by the 20th week. The "small" of small intestine clearly relates only to the circumference of the structure, as its length is anything but small. The small intestine typically measures between 200 and 300 cm at birth in the full-term neonate after doubling its length between 26 and 38 weeks of gestation. After birth, the small intestine continues to grow, finally reaching its maximum length of 600 to 800 cm after 4 years of age.[10] During this time, and continuing through puberty, there are also increases in intestinal diameter, along with development of the plicae circulares, villi, and microvilli that enlarge the absorptive surface area of the small intestine from about 950 cm^2 at birth to 7500 cm^2 in the adult. The blood supply of the small intestine is provided solely by branches of the superior mesenteric artery running in the mesentery of the small intestine.

The circular muscles of the small intestine appear at 6 weeks of gestation and the longitudinal muscles at 8 weeks. Neuroblasts appear at 7 weeks of gestation, and the myenteric and submucosal plexuses are noted to appear between the 9th and 13th weeks. Although there is some peristalsis noted as soon as the plexuses appear, it is poorly coordinated. The appearance of myenteric muscle contractions at 32 to 34 weeks leads to more coordinated contractions, but intestinal transit time at this gestation time is as long as 9 hours—nearly twice as long as in the term infant. It is not until about 38 weeks' gestation that the myenteric muscle contractions are fully present and fasting motor activity is mature. Even so, limited feedings can be accomplished in infants as young as 25 weeks, as they appear to stimulate contractions, albeit immature.

Villi appear during weeks 8 to 11 and acquire their final, finger-like shape by week 14. However, the villi remain shorter in the ileum than in the jejunum, leading to a fourfold greater absorptive area in the jejunum. Microvilli appear and the enterocytes are morphologically mature and display a well-organized brush border by 14 weeks of gestation. Endocrine cells appear at 9 weeks and continue to proliferate, with all the various gut peptide hormones and neurotransmitters present by 20 weeks' gestation. These include enteroglucagon, neurotensin, gastrin, pancreatic polypeptide, motilin, and VIP. Although all are present at birth, many of them show remarkable increases in basal levels during the first 2 weeks of life in the fed infant. Interestingly, when feedings are withheld in infants, intestinal growth and functional maturation are delayed and basal levels of the intestinal peptides remain low, suggesting some form of cause-and-effect relationship.

It is generally held that the enteric ganglion cells are derived from vagal neural crest cells. As mentioned previously, neural crest-derived neuroblasts first appear in the developing esophagus at 5 weeks. They then begin a migration down to the anal canal in a craniocaudal direction during the 5th to 12th weeks of gestation. The neural crest cells first form the myenteric plexuses just outside the circular muscle layer. The mesenchymally derived longitudinal muscle layer then forms, sandwiching the myenteric plexus after it has been formed in the 12th week of gestation. Finally, the submucous plexus is formed by neuroblasts, which migrate from the myenteric plexus across the circular muscle layer and into the submucosa and the mucosa. This also progresses in a craniocaudal direction, but it occurs during the 12th to 16th weeks of gestation.

COLON, RECTUM, AND ANUS

The colon is a continuation of the intestine with two basic functions: (1) the absorption of water and electrolytes and (2) the storage and elimination of feces. Its absorptive function is significant, in that the colon absorbs more than 80% of the water left after passage through the small intestine. The rectum and anus are critical in the complex act of controlled defecation.

The colon is divided into six areas: the cecum, the appendix, and the ascending, transverse, descending, and sigmoid colon. Like the duodenum, the colon also undergoes a 270-degree counterclockwise rotation during the 10th to 12th weeks of gestation to bring it into the proper position.[2] Although this is nearly concurrent with the duodenal rotation, the two are not completely codependent. Either one, or both, can go astray, so it is possible to have a nonrotated colon with a properly rotated duodenum, and vice versa. If properly rotated, the cecum lies in the right lower quadrant, the ascending colon along the right gutter, the transverse colon from the hepatic flexure to the splenic flexure, and the descending colon along the left gutter; the sigmoid colon connects the descending colon to the rectum approximately at the level of the third sacral vertebrae. The ascending colon and the descending colon are retroperitoneal structures with peritoneum covering only their anterior and lateral surfaces. The cecum is variably fixed—sometimes completely retroperitoneal (along with the appendix) and sometimes on a short mesentery. The transverse and sigmoid colon are on a mesentery. The posterior border of the greater omentum is also attached to the transverse colon.

The blood supply of the colon is supplied by both the superior and inferior mesenteric arteries. The watershed area between the distribution of the two vessels is typically located around the mid transverse colon to the splenic flexure. This also marks the boundary of the midgut and hindgut. The rectum is supplied by the inferior mesenteric artery as well as branches off the iliac arteries.

Although it is developmentally similar to the small intestine in general structure, the colon has unique elements. Most obvious is the concentration of the longitudinal muscle coat into three bands—the teniae coli. The teniae create sacculations, called *haustra*, that permit radiographic differentiation of the small from the large intestine after infancy. The mucosa of the colon is characterized by crypts of Lieberkühn, which are lined with absorptive, goblet, and endocrine cells.

The development of the anorectum requires unique attention, because problems result in a wide variety of anorectal malformations. As mentioned previously, during the 3rd week of gestation, the bilaminar germ disc transforms into a trilaminar disc of ectoderm, mesoderm, and endoderm. At either end of the embryo, the endoderm and ectoderm fuse, excluding the mesoderm from these areas and giving rise to the oropharyngeal and cloacal membranes. The former breaks down in the 4th week to give rise to the mouth, whereas the cloacal membrane does not open until the 8th week. Between weeks 4 and 6, it is widely held that the primitive gut tube at the level of the cloacal membrane gets canalized and partitioned into an anterior urogenital sinus and a posterior anorectum by the cranial caudal growth of a mesodermally derived partition called the urorectal septum. Eventually, the urorectal septum fuses with the cloacal membrane, and the fusion site is called the *perineal body*. The newly formed anorectal canal remains closed by the posterior aspect of the cloacal membrane, which is now called the *anal membrane*. The ectoderm in this region then goes on to form the anal pit or proctodeum, so the distal third of the anal canal is eventually made up of ectoderm, the proximal two thirds is made up of mesoderm, and the two cell types are divided by the anal membrane. The membrane breaks down during week 8, and the two cell populations fuse at what is called the *pectinate* or *dentate line*.

Aside from the previously described migration of neural crest cells to form enteric ganglion cells, the anorectum has an important neurologic milestone during the 4th week of gestation. At this time, spinal nerves from sacral levels 2, 3, and 4, which contribute to the peripheral parasympathetic nervous system, form. In contrast to the motility problems noted with failure of migration and thus the absence of ganglion cells, problems related to the proper development of these spinal nerves during week 4 may lead to the proprioceptive and motility problems associated with anorectal malformations.

PART 2

Disorders of Digestion

Shaista Safder, Sundeep Arora, and Gisela Chelimsky

Neonates can present with a variety of problems pertaining to the digestive tract. The major focus of this chapter is to discuss the disorders that will affect neonates and infants in the achievement of good weight gain. This review is an overview of the evaluation and management of the newborn who presents with symptoms of poor weight gain, diarrhea, or malabsorption.

The main clinical expression of malabsorption is diarrhea. Diarrhea, when chronic, results in malnutrition and failure to thrive. Chronic diarrhea starting in the hours and days following birth is usually extremely severe, leading in a few weeks to life-threatening malnutrition. Malabsorption syndromes are characterized by the association of chronic diarrhea, abdominal distention, and failure to thrive.

INFANTILE DIARRHEA

In 1968, Avery and colleagues coined the term *intractable diarrhea of infancy* to define an entity characterized by the appearance of diarrhea in an infant younger than 3 months, lasting more than 2 weeks, with three or more negative stool cultures, and requiring long-term parenteral nutrition and possibly intestinal transplant for survival.[9] Little has changed in this definition since then. Intractable diarrhea of infancy should be contrasted with protracted diarrhea of infancy, which resolves despite its initial severity.[160]

Evaluation of the Infant with Chronic Diarrhea

The evaluation of the infant with chronic diarrhea should include a careful prenatal history, past medical history, feeding history, family history, a detailed physical examination, and then evaluation. For example, infants who are not breast fed are at increased risk to develop persistent diarrhea whereas breast feeding is a protective factor.[72] Table 47-1 summarizes the key points to be considered in the evaluation of infants and children with chronic diarrhea. Table 47-2 summarizes many of the causes of chronic diarrhea. In the evaluation of chronic diarrhea, it is important to differentiate between secretory and osmotic diarrhea. On many occasions, the diarrhea can be a result of a combination of both mechanisms, for example, in tufting enteropathy, phenotypic diarrhea, and diarrhea due to immunodeficiencies. The classification of secretory and osmotic diarrhea is based on the persistence of diarrhea in the absence of feeds and on the fecal osmolar gap. *Secretory diarrhea* is described as large volumes of watery stools that persist in the absence of enteral feeds, whereas osmotic diarrhea is dependent on enteral feeds and stool volumes are not as massive as in secretory diarrheas.

Secretory diarrheas are characterized by increased electrolytes and water fluxes toward the lumen secondary to either a block in intestinal absorption of NaCl or increase in chloride

TABLE 47–1 Approach to Infant with Diarrhea and Poor Weight Gain

Prenatal history	Polyhydramnios consistent with congenital sodium and chloride diarrhea
Past medical history	Surgeries, history of necrotizing enterocolitis, chronic liver disease
Physical examination	Emphasis on skin manifestations such as those with acrodermatitis enteropathica, facial features, and woolly hair of phenotypic diarrhea Evaluation of nutritional status and intervention for nutritional support
Family history	Important in elucidating a genetic cause for congenital diarrheas. A family history of immune or atopic disease would point to allergy or autoimmunity, or family history of cystic fibrosis.
Infectious workup (regardless of risk factors)	Stool cultures, stool parasites, and enteric viruses
Biochemical markers	Albumin, prealbumin, iron, micronutrient assessment
Test for etiology based on pathophysiology of diarrhea (secretory versus osmotic)	Measure osmotic gap, stool electrolytes for sodium and chloride, stool pH
Test for intestinal function	Stool α_1-antitrypsin, fecal elastase, stool-reducing substance, stool fat, stool for occult blood, stool for fecal leukocytes, fecal calprotectin
Structural evaluation	Endoscopy and histology Electron microscopy indicated in all forms of intractable diarrheas of unknown etiology to evaluate ultrastructural abnormalities
Immunohistochemistry	Evaluate mucosal immune activation,[27] study smooth muscle cells, neuronal cells, enterocytes, and components of basal membrane
Abdominal imaging	Evaluate anatomy

TABLE 47–2 Classification of Diarrheas and Malabsorption Syndromes

Pancreatic insufficiency	Cystic fibrosis, Shwachman-Diamond syndrome, Johanson-Blizzard syndrome, Donlan syndrome, Pearson syndrome, Jeune syndrome
Carbohydrate malabsorption	Disaccharides deficiency, congenital lactase deficiency, glucose-galactose malabsorption, maltase-glucoamylase deficiency
Protein malabsorption	Primary intestinal enteropeptidase deficiency, primary trypsinogen deficiency, lysinuric protein intolerance, primary intestinal lymphangiectasia
Fat malabsorption	Hypobetalipoproteinemia, abetalipoproteinemia, chylomicron retention disease Bile acid malabsorption
Electrolyte transport defects	Congenital chloride diarrhea, congenital sodium diarrhea
Villous architectural defects	Microvillous inclusion disease, tufting enteropathy, autoimmune enteropathy (IPEX), infectious enteropathy
Infantile intractable diarrhea	Syndromic or phenotypic diarrhea
Miscellaneous conditions	Acrodermatitis enteropathica, hormone-mediated secretory diarrhea, short gut syndrome
Motility disorders, usually associated with small intestinal bacterial overgrowth	Intestinal aganglionosis (long segment Hirschsprung disease) or chronic intestinal pseudo-obstruction syndrome
Immune mediated	Allergic enteropathy

secretion by secretory crypt cells. Examples of this kind of diarrhea are congenital Na and Cl diarrhea, microvillus inclusion disease, and autoimmune enteropathy.

Osmotic diarrheas generally occur when digestion and/or absorption is impaired. They are caused by nonabsorbed nutrients in the gastrointestinal tract and are generally associated with intestinal damage. The osmotic force driving water into the lumen is derived from nonabsorbable solutes from food or injured mucosa. Absence or reduction in pancreatic enzymes and bile acid disorders cause impaired digestion of carbohydrate, protein, and fat, contributing to this kind of diarrhea (Table 47-3). Infectious agents can cause diarrhea either by a secretory or osmotic mechanism.

The kind of diarrhea can also be differentiated by measuring the stool osmolality and the fecal osmolar gap. The normal fecal osmolality is similar to the plasma osmolality (i.e., 290 mOsm/kg).[35,36] The fecal osmolar gap is calculated by subtracting twice the sum of fecal sodium and potassium (to account for anions) from the fecal osmolality. It is important that the fecal electrolytes be measured on a freshly collected specimen.

TABLE 47–3 Components Required for Digestion of Macronutrients

Carbohydrates	Pancreatic amylase, glucoamylase, intestinal disaccharidases (maltase, sucrase, lactase), glucose transporters, colonic bacteria
Protein	Gastric pH, pepsin (stimulated by gastrin), chymotrypsin and trypsin (activated by enterokinase), dipeptidase, amino acid transporters
Fat	Bile acids, pancreatic lipase, chylomicron formation in enterocytes

$$\text{Fecal osmolar gap} = 290\ \text{mOsm/kg} - [2\ (\text{Na}^+ + \text{K}^+)]$$

	Secretory diarrhea	Osmotic diarrhea
Osmotic gap	<50 mOsm/kg	>135 mOsm/kg
pH	>6	<5
Na concentration	>70 mEq/L	<70 mEq/L
Cl concentration	>40 mEq/L	<35 mEq/L

In secretory diarrhea, the fecal osmolar gap is usually less than 50, whereas in osmotic diarrhea, it is greater than 50.[15] It is important in the evaluation of the child with diarrhea to quantify stool output, even if this entails placing a urinary catheter to separate urine from stools. Another way to collect stools is to have the child wear one diaper inside out, surrounded by a second diaper in the usual fashion to absorb any stool that runs out.

Diarrhea can also be categorized based on the location of the disorder, either as a luminal or epithelial disorder. Among the luminal causes, alteration in intestinal transit times and surgical removal of absorptive surface of bowel contributes to diarrhea and malabsorption such as that seen in short gut syndrome.

Management of Intestinal Failure

Intestinal failure is a condition in which there is insufficient functional bowel to allow for adequate nutrient and fluid absorption to sustain adequate growth in children, necessitating parenteral nutrition. There can be medical and surgical causes for intestinal failure. Surgical causes include patients with necrotizing enterocolitis, intestinal atresias, and midgut volvulus, among others. Many of these conditions do not intrinsically cause intestinal failure, but their natural histories often mandate surgical resection of bowel leading to short bowel syndrome and its complications. Medical causes of intestinal failure include infants with dysmotility disorders[29] or patients with severe intractable diarrheas. Children with surgical causes of intestinal failure have greater potential for bowel adaptation than children with medical causes of intestinal failure.[29] Patients with intestinal failure need intestinal rehabilitation which can be seen as a three-pronged strategy merging nutrition, pharmacologic, and surgical approaches to achieve the ultimate goal of enteral nutrition in these children. Intestinal transplantation is indicated in patients in whom long-term parenteral nutrition cannot be performed safely. Common reasons for intestinal transplantation include short bowel syndrome, congenital mucosal diseases, and motility disorders.[131] In children with intestinal failure, transplantation must be discussed early, and should evolve from being a rescue procedure to becoming a true therapeutic option.[131]

DISORDERS OF PANCREATIC INSUFFICIENCY

Cystic Fibrosis

Cystic fibrosis (CF) is one of the most common fatal genetic disorders.[28] It is an inherited disease of epithelial cell ion transport, and it is the most common cause of exocrine pancreatic insufficiency and severe progressive lung disease in childhood.[48] This disease was considered uniformly fatal, but with advances in management, the median survival today is estimated at 40 years.[137]

INCIDENCE

Cystic fibrosis is estimated to affect between 1 in 1900 and 1 in 3700 live births in the white population,[137] with a much lower frequency among African Americans (1 in 17,000)[137] and even lower in Asian populations (1 in 90,000).[28] Other geographic areas with higher incidences are Northern Ireland (1 in 1700) and Sweden (1 in 7700). As a result of inbreeding, certain areas have a higher than average incidence, such as 1 in 377 in Britain and 1 in 640 among the American Amish.[137] Nevertheless, CF is always considered in the differential for any child with the constellation of poor weight gain and chronic lung disease, irrespective of the race or the geographic origin of the patient.[122]

GENETICS

Cystic fibrosis is transmitted in an autosomal recessive manner.[48] In the white population, approximately 1 in 20 individuals carries the recessive form of the allele.[38] Thus, if both parents are CF carriers, there is a 25% chance of having an affected child, a 50% chance of having a carrier, and a 25% chance of having an unaffected child.[28]

MOLECULAR PATHOGENESIS

Kerem and colleagues[75] were successful in cloning the gene responsible for CF in 1989. This gene was mapped to chromosome 7 and was found to encode for a large, single-chain protein that forms a chloride channel with its associated regulatory regions, named the cystic fibrosis transmembrane regulator.[48] More than 800 different mutations have been described, of which the most important is the delta F508 mutation.

CLINICAL FEATURES

Affected newborns present with intestinal obstruction resulting from thick meconium plugs obstructing the ileum, also known as *meconium ileus*.[137] Abdominal radiography demonstrates dilated small bowel loops associated with bubbles of gas and meconium in the absence of air-fluid levels, also described as a ground-glass appearance (Neuhauser sign).[122] Other findings include a small-caliber colon (microcolon).[160] Half of the affected infants present with complications such as peritonitis, volvulus, atresia, and necrosis, which may be noted as calcifications on a plain abdominal radiograph.[122] Meconium plug syndrome, a transient distal colonic obstruction that is relieved by the passage of a meconium plug, signifies the possibility of CF.[122]

Extrahepatic biliary duct obstruction resulting from thick inspissated bile plugs or long-term parenteral nutrition support can result in prolonged conjugated hyperbilirubinemia.[122] Thus, sweat chloride is part of the workup of any neonate with prolonged conjugated hyperbilirubinemia.[137] A small percent of children (2% to 5%) present with symptomatic portal hypertension.[73] Poor weight gain is almost universal in patients with CF who have pancreatic insufficiency.[122] Respiratory symptoms include cough, wheezing, retractions, and tachypnea, with a variable degree of atelectasis on chest radiograph that typically presents later.[73]

DIAGNOSIS

The diagnosis is usually established by a supportive history along with laboratory investigations. Sweat chloride in excess of 60 mEq/L is diagnostic.[137] Ninety-nine percent of patients with CF have elevated sweat chloride concentrations.[137] However, conditions such as hypothyroidism, Addison disease, ectodermal dysplasia, glycogen storage disease, and technical errors such as evaporation and contamination may falsely elevate sweat chloride values. Likewise, edema, malnutrition, and sampling errors may give falsely negative values.[28,137] Thus it is important to carry out this test at a center certified by the Cystic Fibrosis Foundation.[28] Genotyping with commercially available tests can identify 80 common mutations in the cystic fibrosis transmembrane regulator, including delta F508, and can also be used when adequate sweat is difficult to obtain.[140]

Another measure of pancreatic insufficiency that is easily performed, inexpensive, and reproducible with a high sensitivity and specificity, is the measurement of fecal elastase 1 (E1).[146] Nissler and coworkers[101] established reference ranges after measuring E1 from the stool samples of 148 children. For an infant older than 2 weeks, E1 above 200 μg/g of feces is adequate, and less than 100 μg/g of stool is a measure of insufficiency.[101] Figure 47-2 describes the currently suggested evaluation in children with concerns for cystic fibrosis.

PRENATAL DIAGNOSIS

On the basis of the CF carrier status of the parents, a prenatal diagnosis can be established by mutational analysis of fetal cells obtained by chorionic villus sampling at 10 weeks of gestation or by amniocentesis at 15 to 18 weeks of gestation. If the pregnancy is carried to term, the neonate should be tested by sweat chloride analysis for confirmation.[122] Other radiologic signs that may be suggestive of CF include a

hyperechoic fetal bowel pattern, meconium peritonitis, and abdominal calcifications.[137]

MANAGEMENT

Management of the patient with CF is a multidisciplinary team effort involving the participation of a gastroenterologist, a pulmonologist, a nutritionist, and a social worker.[160] Attention must be focused on supplying adequate calories, replacing fat-soluble vitamins, and providing supportive care.[122] Pancreatic enzyme replacements have long been used and are generally well tolerated. However, the dosage should not exceed 50,000 U lipase per kilogram because of concerns of fibrosing colonopathy.[132]

Pulmonary disease is the main cause for late morbidity and mortality associated with CF. Clinical trials are underway to evaluate the potential for gene therapy as being the definitive treatment for CF pulmonary disease.

Shwachman-Diamond Syndrome

The Shwachman-Diamond syndrome complex,[31] characterized by exocrine pancreatic insufficiency, bone marrow failure, and skeletal changes, was originally described independently by Nezelof and Watchi (1961),[97] Bodian and colleagues in the United Kingdom (1964),[17] Burke and coworkers in Australia (1967),[20] and Shwachman in the United States (1964).[141] It is a very rare disorder of pancreatic insufficiency, but its importance is that it is the second most common cause of bone marrow failure after cystic fibrosis; the third most common cause is Fanconi, followed by Diamond-Blackfan anemia.[32]

INCIDENCE

The estimated incidence in the North American population is about 1 in 50,000. Recent reports have noted the existence of Shwachman-Diamond syndrome in European, Asian, and African population cohorts.[160]

GENETICS

An autosomal recessive mode of inheritance has been proposed by observation of different family pedigrees. In 2002, researchers from Toronto identified the gene that is altered in Shwachman-Diamond syndrome and the locus has been mapped to chromosome 7.[33] Unlike Fanconi anemia, which may result from mutations in more than five different genes, and Diamond-Blackfan anemia (25% of families have mutations in the RPS19 gene), more than 90% of the Shwachman-Diamond syndrome patients had alterations in one single gene on chromosome 7. The SBDS gene (named after Shwachman-Bodian-Diamond), located on 7q11, is predicted to code for a 250 amino acid protein of (currently) unknown function. The transcript of the normal gene is widely expressed in the pancreas, bone marrow, and leukocytes and assumed to be necessary for the normal development of these tissues.[51]

CLINICAL FEATURES

The disease is highlighted by failure to thrive in infancy associated with exocrine pancreatic insufficiency and varying degrees of bone marrow failure.[123] Pancreatic insufficiency results in malabsorption and steatorrhea, which in turn results in poor weight gain.[160] Neutropenia with defective neutrophil chemotaxis is the most common hematologic abnormality which results in frequent bacterial infections such as otitis media and pneumonia.[31] Neutropenia is characteristically intermittent, with cycles of low to normal values.[32] Anemia and thrombocytopenia have also been described in patients with Shwachman-Diamond syndrome.[160] Bone marrow is hypocellular and is replaced with fatty infiltration.[33] When a case of Shwachman-Diamond syndrome is suspected, the diagnostic criteria listed in Table 47-4 should help establish the diagnosis. The presence of skeletal abnormalities, short stature, and hepatic impairment would support the diagnosis.

MANAGEMENT

The following recommendations for managing Shwachman-Diamond syndrome were outlined at the 3rd International Congress on Shwachman-Diamond syndrome in June 2005, Cambridge, UK.[51]

Gastrointestinal

As in cystic fibrosis, the pancreatic insufficiency is treated with pancreatic enzyme supplements, fat-soluble vitamins, and a high caloric diet. The enzyme dose should be regulated according to symptoms, such as steatorrhea, abdominal pain, and growth parameters.

Hematologic

Febrile neutropenia or overt infection is treated with broad-spectrum antibiotics. Granulocyte colony-stimulating factor (G-CSF) can be used, but is usually reserved for cases of severe life-threatening sepsis and rarely as prophylaxis. Blood and platelet transfusions are given as required for anemia and thrombocytopenia.

Johanson-Blizzard Syndrome

Johanson-Blizzard syndrome (JBS) is a rare autosomal recessive disorder that was first described in 1971 by Johanson and Blizzard.[69] Only about 30 cases have been described in

TABLE 47–4 Diagnostic Criteria for Shwachman-Diamond Syndrome[31]

Exocrine pancreatic insufficiency (at least one of the following)	Abnormal quantitative pancreatic stimulation test Serum cationic trypsinogen below normal range Abnormal 72-hour fecal fat Evidence of pancreatic lipomatosis by computed tomography or ultrasound
AND	
Hematologic abnormalities (at least one of the following)	Chronic single lineage or multi-lineage cytopenia Neutrophil less than 1.5×10^9/L Hemoglobin less than 2 standard deviations below mean Thrombocytopenia less than 150×10^9/L Myelodysplastic syndrome

the literature.[32] This disorder is characterized by multisystem involvement.[39] More than a dozen subjects have positional cloning identified loss-of-function mutations in the *UBRI* gene on the long arm of chromosome 15.[167] In patients with Johanson-Blizzard syndrome, the absence of *UBRI* results in early prenatal destruction of the exocrine pancreas that involves impaired apoptosis, induced necrosis, and prominent inflammation.

Affected infants have characteristic phenotypic features, including aplastic alae nasi (which gives the appearance of a beaklike nose with large nostrils),[8] extension of the hairline to the forehead with upswept frontal hair,[50] low-set ears, large anterior fontanelle, micrognathia, thin lips, microcephaly,[39] aplasia cutis (patchy distribution of hair with areas of alopecia), dental anomalies, postnatal growth restriction and pancreatic exocrine aplasia, and anorectal anomalies (predominantly, imperforate anus).[8,151] Other features include mental retardation, deafness, genitourinary abnormalities, hypothyroidism, and cardiac malformations.[8] These infants have significant intrauterine growth restriction because of the lack of insulin resulting from pancreatic insufficiency,[50] and they grow up to exhibit dwarfism. Takahashi and colleagues described a neonate with a diagnosis of Johanson-Blizzard syndrome whose poor growth was determined to be caused by growth hormone deficiency.[151] This patient also demonstrated poor glucagon secretion in response to hypoglycemia. Al-Dosari reported a case of an infant with classic Johanson-Blizzard syndrome who also had unusually severe neonatal cholestatic liver disease that progressed to liver fibrosis and portal hypertension.[3]

As a result of exocrine pancreatic insufficiency, affected patients present with severe malabsorption, which leads to poor weight gain, failure to thrive, hypoalbuminemia, edema, and anemia.[8] Prenatally, diagnosis has been suggested by ultrasonographic findings of beaklike nose and of dilation of sigmoid colon as a result of imperforate anus.[8] Affected individuals have a normal karyotype[8] as well as normal sweat chloride. The presence of anatomic dysmorphisms, exocrine pancreatic insufficiency, and normal sweat chloride distinguishes this condition from cystic fibrosis.

Miscellaneous Causes of Pancreatic Insufficiency

Many other syndromes and diagnoses can be associated with pancreatic insufficiency. Donlan syndrome is similar to JBS, with the notable exception of the presence of normal alae nasi and cleft palate.[50] Pearson syndrome is characterized by features of pancreatic insufficiency, sideroblastic anemia,[50] variable neutropenia, thrombocytopenia, and vacuolization of bone marrow precursors.[160] Jeune syndrome is a rare autosomal recessive disorder of pancreatic insufficiency and asphyxiating thoracic dystrophy.[160] Isolated deficiencies of amylase, lipase, colipase, and trypsinogen have also been described. Familial pancreatitis with mutations in the trypsinogen gene can cause chronic pancreatitis, pancreatic insufficiency, and chronic diarrhea.

DISORDERS OF CARBOHYDRATE ABSORPTION

The enterocytes lining the small intestine have, at their apical surface brush border, various enzymes responsible for digestion of carbohydrates.[160] These carbohydrate hydrolases convert disaccharides and oligosaccharides into simple monosaccharides that are absorbed easily via transport proteins that exist on the intestinal surface.[98] Examples include maltase-glucoamylase, sucrase-isomaltase (SI), and lactase-phlorhizin hydrolase.[99] The clinical symptoms of carbohydrate malabsorption occur either because of the deficiency of a particular enzyme (e.g., congenital sucrase-isomaltase deficiency) or because of an abnormality in a transport protein involved with the absorption of digestion product (e.g., glucose-galactose malabsorption). There is often a correlation between the age a disorder appears and the age at which a particular food is introduced into the baby's diet (Table 47-5).

Patients with carbohydrate malabsorption disorders, regardless of the cause, present with severe watery diarrhea, which results from osmotic action exerted by the malabsorbed oligosaccharide,[160] that is, lactose, sucrose, or glucose, in the intestinal lumen. An important aspect is the regression of diarrhea when oral feeds are discontinued. The malabsorbed sugars are in turn acted on by colonic bacteria, generating a mixture of gases (e.g., hydrogen, methane, and carbon dioxide),[160] along with short-chain fatty acids. The gases form the basis of carbohydrate-specific breath hydrogen testing, which is often used in diagnosis.[121] The short-chain fatty acids are absorbed via the colonic epithelium, and they not only provide energy but also help decrease the colonic osmolality. In the presence of a large carbohydrate load, these protective mechanisms become overwhelmed, leading to worsening of the diarrhea.[160] The increased volume, coupled with low pH, stimulates gut motility and decreases intestinal transit time.[74]

Disaccharidase Deficiencies

CONGENITAL SUCRASE-ISOMALTASE DEFICIENCY

Congenital sucrase-isomaltase deficiency is the most common congenital disorder of carbohydrate malabsorption.[90] It is characterized by decreased activity of the enzyme responsible for hydrolysis of dietary sucrose[11] in the brush border epithelium of the small intestine. It is transmitted in an autosomal

TABLE 47–5 Age of Onset of Different Malabsorption Syndromes

Age of Onset	*Disorder*
Immediate neonatal period	Glucose-galactose malabsorption Congenital lactase deficiency
Weaning age	Glucoamylase deficiency Congenital sucrase-isomaltase deficiency

recessive form[119] and has been mapped to chromosome 3.[90] A higher prevalence has been noted among congenital sucrase-isomaltase deficiency populations of Canadian, native Alaskan, and Greenlander descent (3% to 10%)[90] compared with native North Americans (0.2%).[160]

Etiology

Congenital sucrase-isomaltase deficiency is caused by reduced activity of the brush border enzyme sucrase-isomaltase.[119] Several theories have been proposed for the pathogenesis of this enzyme deficiency. A point mutation in the *SI* gene,[105] resulting in substitution of glutamine by arginine at position 117,[147] interferes with its transport out of the endoplasmic reticulum and the Golgi bodies, resulting in intracellular accumulation and degradation. The sucrase-isomaltase (SI) gene from 11 patients of Hungarian origin with congenital sucrase-isomaltase deficiency was examined by Sander and colleagues.[130] Analyses revealed 43 *SI* variants in total, 15 within exons and one at a splice site. Eight of the exonic mutations lead to amino acid exchanges, causing null alleles. One new variation affects a splice site, which is also predicted to result in a null allele. All potential pathologic alterations were present on one allele only. In 6 of the 11 patients, the phenotype of congenital sucrase-isomaltase deficiency was accounted for by compound heterozygosity.[130]

Clinical Features

The patient presents with diarrhea, usually noticed around the age of 3 to 6 months when the infant is weaned from breast milk to baby foods that contain sucrose. If the baby has been switched to a sucrose-containing formula (e.g., Isomil), diarrhea is noted earlier. Affected infants present with severe, chronic or intermittent watery diarrhea, abdominal distention, cramping,[153] and failure to thrive.[11] The stool pH is noted to be less than 7 as a result of fermentation by colonic bacteria, but because sucrose is a nonreducing sugar, Clinitest or a test for stool reducing substances is negative.[90]

Diagnosis and Treatment

The history from the caregiver should describe feedings, formula changes, age at weaning, and age of onset of diarrhea. Patients present with severe watery diarrhea, metabolic acidosis, and poor weight gain.[11] Stools are acidotic but test negative for reducing substances. Stool osmolality reveals an elevated osmolar gap (greater than 50 mOsm), indicating the presence of malabsorbed sugars. Sucrose hydrogen breath testing[52] offers a noninvasive assessment, but the results must be interpreted in the light of other clinical findings, as secondary disaccharidase deficiency is a known consequence of mucosal injury from any cause.[90] Endoscopy, with analysis of duodenal biopsies for actual enzyme levels, is the gold standard for diagnosis. The treatment of congenital sucrase-isomaltase deficiency is highlighted by strict lifelong avoidance of sucrose-containing fruits and beverages.[90]

CONGENITAL LACTASE DEFICIENCY

Congenital lactase deficiency is an exceedingly rare autosomal recessive disorder. Patients present with watery diarrhea, vomiting, poor weight gain, lactosuria, aminoaciduria, and nervous system changes in the days after birth.[65,85] A majority of the patients described in the literature are from Finland, where more than 42 cases[65] have been described since the first diagnosis in 1959.[61]

Congenital lactase deficiency is caused by the deficiency of lactase, a disaccharidase in the small intestine that has been linked to 2q21.[65] Villous architecture of the intestinal mucosa is preserved, as noted on biopsy specimens of the small intestine.[160] However, congenital lactase deficiency is different from adult-type hypolactasia, which is caused by decreased activity of the lactase-phlorhizin hydrolase enzyme, which resides more than 2 Mb away from the congenital lactase deficiency locus.[65] Usually, congenital lactase deficiency is an isolated deficiency, but as reported by Nichols and colleagues, it may be associated with deficiencies of other disaccharidases such as maltase-glucoamylase.[98]

The appearance of the watery diarrhea coincides with the introduction of lactose-containing milk (either in breast milk or in lactose-based commercial formulas) into the baby's diet, and it is usually noticed within the first 10 days.[65] The stool pH is less than 7 as a result of fermentation of the malabsorbed lactose by colonic bacteria. The diarrhea resolves after switching to a lactose-free formula,[160] which clinches the diagnosis. Apart from diarrhea, these babies are lively and have a good appetite; they exhibit poor weight gain but no vomiting.[128] Saarela and colleagues described 11 infants with congenital lactase deficiency who were found to have hypercalcemia and nephrocalcinosis.[128] The hypercalcemia probably resulted from either metabolic acidosis or enhanced calcium absorption in the ileum, as facilitated by nonabsorbed lactose. Interestingly, the hypercalcemia was corrected after a lactose-free diet was instituted.[128] As a result of metabolic acidosis, a decreased urinary excretion of citrate is noted.[106] Thus hypercalcemia in the presence of hypocitruria sets the stage for nephrocalcinosis.

Congenital lactase deficiency can be diagnosed by its classic presentation, and it can be objectively demonstrated by the lack of a rise of blood reducing sugars after an oral load of lactose.[85] Patients have flat lactose tolerance curves with a normal elevation of blood sugar after the administration of individual monosaccharides and other disaccharides.[85] The diagnostic gold standard is quantification of the enzyme levels from duodenal biopsy specimens,[160] but this may not be possible in all cases.[85]

Treatment consists of avoidance of lactose-containing formula for the neonate. Patients with congenital lactase deficiency have good catch-up growth with normal psychomotor development when maintained on a lactose-free diet.

MALTASE-GLUCOAMYLASE DEFICIENCY

Maltase-glucoamylase is a brush border hydrolase[98] that serves as an alternate pathway for starch digestion. It compensates partially for the lack of sucrase-isomaltase.[160] Congenital maltase-glucoamylase deficiency, first described in 1994, is very rare,[99] with an estimated incidence of 1.8% among children who are investigated for congenital diarrhea. Maltase-glucoamylase bears a striking similarity to SI (59% homology), and it has two catalytic sites that are identical to those of SI.[98] Thus it is not uncommon to see maltase-glucoamylase deficiency in patients with congenital sucrase-isomaltase deficiency.

Clinical Features

Patients present with diarrhea, abdominal distention, and bloating. Symptoms usually coincide with the introduction of starch into the infant's diet at the time of weaning.[160]

Diagnosis and Treatment

Diagnosis is usually established by demonstrating decreased levels of the enzyme on intestinal biopsies. Affected infants should be fed lactose-free formulas. Starch elimination is helpful beyond the neonatal period.[160]

Transport Defects

GLUCOSE-GALACTOSE MALABSORPTION

Glucose-galactose malabsorption is a rare disorder. Patients present with severe watery diarrhea in the neonatal period, which can lead to rapid dehydration and death.[160] It is clinically indistinguishable from congenital lactase deficiency.[106] It was reported in 1962 by Lindquist and Meeuwisse in Sweden.[86] It is transmitted in an autosomal recessive manner.[152]

Incidence

Glucose-galactose malabsorption is rare, and its highest prevalence occurs among populations with a high rate of consanguineous marriages. Approximately 300 cases have been described in the literature worldwide.[160]

Molecular Pathophysiology

Glucose-galactose malabsorption stems from a defect in the intestinal glucose-galactose transport protein, SGLT1.[160] SGLT1 transports glucose and galactose, intracellularly coupled with Na^+, using an electrical gradient to transport against the concentration gradient.[106] It has been mapped to chromosome 22, and mutation analysis is possible. Kianifar and colleagues reported D28G mutations in family members of a patient with glucose-galactose malabsorption using the polymerase chain reaction restriction fragment length polymorphism method.[76]

Clinical Features

Affected infants present with severe watery diarrhea, urine-like in appearance, and coinciding with the start of breast-feeding or ingestion of glucose-containing formula.[160] The predominant sugar of breast milk is lactose, which is hydrolyzed to glucose and galactose prior to being absorbed. The diarrhea can lead to rapid dehydration and electrolyte imbalance.[152] The malabsorbed sugar behaves like an osmotic agent, resulting in diarrhea, which is acidic because of fermentation by colonic bacteria.[160] If prompt attention is not paid to the correction of fluid and electrolyte imbalances, glucose-galactose malabsorption can be rapidly fatal. Stools test positive for reducing substances, indicating malabsorption of reducing sugars.[106] The results of an oral glucose tolerance test demonstrate a flat glucose tolerance curve with the presence of glucose in stools. Endoscopy and colonoscopy show normal colonic and small bowel histology. The onset of diarrhea after the introduction of glucose, the presence of glucose in stools, hypoglycemia, hypernatremic dehydration, and normal intestinal morphology clinch the diagnosis. Because SGLT1 is also expressed in renal tubular cells, patients may also have glucosuria.[106] Case reports of nephrocalcinosis and urinary calculus formation in patients with glucose-galactose malabsorption have been described in the literature.[106,152] The mechanisms responsible for renal stone formation, as explained earlier for congenital lactase deficiency, may exist in glucose-galactose malabsorption. As with congenital lactase deficiency, hypercalcemia resolved after a glucose-free diet was instituted and diarrhea was controlled.[106]

Diagnosis and Treatment

Diarrhea that improves on elimination of glucose, galactose, and lactose from the diet, coupled with a positive glucose breath hydrogen test and a normal intestinal biopsy, establishes the diagnosis.[160] Infants with glucose-galactose malabsorption can be safely treated with fructose-containing formula, because fructose is absorbed via a different carrier, GLUT5, which is unaffected.[106]

DISORDERS OF PROTEIN ABSORPTION

Primary Intestinal Enteropeptidase Deficiency

Enteropeptidase, formerly known as *enterokinase*, resides in the proximal small intestine and belongs to the group of serine proteases.[62] This enzyme plays a key role in the initiation of protein digestion in the small intestine by bringing about the conversion of trypsinogen to active trypsin, which in turn activates other pancreatic zymogens.[45] It was initially described in 1969 and very few cases are known worldwide. Affected infants present with diarrhea, failure to thrive, and protein-losing enteropathy.[11] When the edema that resulted from hypoproteinemia gets remarkably better after the baby is switched from an intact-protein-based formula to a protein-hydrolysate formula, the diagnosis is confirmed.[160]

Congenital enteropeptidase deficiency is a rare recessively inherited disorder. The genomic structure of the proenteropeptidase gene (25 exons, total gene size 88 kb) was characterized in order to perform DNA sequencing in three clinically and biochemically proved patients with congenital enteropeptidase deficiency who were from two families. Holzinger and associates found compound heterozygosity for nonsense mutations (S712X/R857X) in two affected siblings and found compound heterozygosity for a nonsense mutation (Q261X) and a frameshift mutation (FsQ902) in the third patient. In accordance with the biochemical findings, all four defective alleles identified were predicted null alleles leading to a gene product not containing the active site of the enzyme.[62] These data provide first evidence that proenteropeptidase-gene mutations are the primary cause of congenital enteropeptidase deficiency.[62]

LABORATORY INVESTIGATIONS

Affected infants present with watery diarrhea with normal osmolality and absent osmolar gap, suggesting transport defects. The serum hypoalbuminemia and hypoproteinemia are striking. Enteropeptidase deficiency can be demonstrated either by quantification of the enzyme levels on small intestinal biopsies or by assaying enzyme levels in the duodenal fluid.[45]

TREATMENT

Once the diagnosis has been established, the infant should be switched to protein-hydrolysate formula.[160]

Primary Trypsinogen Deficiency

Primary trypsinogen deficiency results in clinical symptoms very similar to those of primary enteropeptidase deficiency. It is usually described in children with cystic fibrosis who have pancreatic exocrine deficiency.[160]

Lysinuric Protein Intolerance

Lysinuric protein intolerance, also known as *hyperdibasic aminoaciduria type 2* or *familial protein intolerance*,[107] is a disorder of amino acid transport that is characterized by subnormal plasma levels of dibasic amino acids, such as ornithine, arginine, and lysine, and their enhanced urinary excretion. This disorder is transmitted in an autosomal recessive manner and is found at a higher prevalence in three main geographic areas: Finland, Italy, and Japan.[107] Affected patients usually present around the time of weaning, when they are switched from breast feeding to high-protein foods.[107] Citrulline supplementation (200 mg/kg per day) and a protein-restricted diet (1.5 g/kg per day) are the mainstays of therapy.[160]

Primary Intestinal Lymphangiectasia or Waldmann Disease

In 1961, Waldmann and coworkers described the first 18 cases of idiopathic hypercatabolic hypoproteinemia.[159] These patients had edema associated with hypoproteinemia and low serum albumin and gammaglobulin levels. Microscope examination of the small intestine biopsies showed variable degrees of dilation of the lymph vessels in the mucosa and submucosa. The authors also proposed the term *intestinal lymphangiectasia*.[159]

Primary intestinal lymphangiectasia is a rare disorder characterized by dilated intestinal lacteals resulting in lymph leakage into the small bowel lumen and responsible for protein-losing enteropathy leading to lymphopenia, hypoalbuminemia, and hypogammaglobulinemia. Primary intestinal lymphangiectasia is generally diagnosed before 3 years of age but may be diagnosed in older patients. Prevalence is unknown.

Primary intestinal lymphangiectasia may be suspected at birth or during pregnancy based on ultrasonography images, which can detect fetal ascites or lower limb lymphedema.[133]

ETIOLOGY

To date, primary intestinal lymphangiectasia etiology is unknown. Intestinal lymphangiectasia is responsible for lymph leakage into the bowel lumen, which leads to hypoalbuminemia and lymphopenia. Edema is the consequence of hypoproteinemia with decreased oncotic pressure. Several genes, such as *VEGFR3* (vascular endothelial growth factor receptor 3), prospero-related homeobox-transcriptional factor *PROX1*, forkhead transcriptional factor *FOXC2*, and *SOX18* are implicated in the development of the lymphatic system. In a recent paper, Hokari and colleagues reported inconsistently changed expressions of regulatory molecules for lymphangiogenesis in the duodenal mucosa of patients with primary intestinal lymphangiectasia.[59]

CLINICAL FINDINGS

The main symptom is peripheral edema of variable degree, usually symmetric, from moderate (lower limb edema) to severe, including the face and external genitalia.[82] Edema may be moderate to severe with anasarca and includes pleural effusion, pericarditis, and chylous ascites. Fatigue, abdominal pain, weight loss, inability to gain weight, moderate diarrhea, and fat-soluble vitamin deficiencies due to malabsorption may also be present. In some patients, limb lymphedema is associated with primary intestinal lymphangiectasia and is difficult to distinguish lymphedema from edema. Moderate diarrhea is the main digestive symptom.[83]

Five syndromes are associated with intestinal lymphangiectasia: von Recklinghausen, Turner (X0), Noonan, Klippel-Trenaunay, and Hennekam.[55]

DIAGNOSIS

Primary intestinal lymphangiectasia diagnosis is confirmed by the presence of intestinal lymphangiectasia based on endoscopic findings with the corresponding histology of intestinal biopsy specimens.[158] Protein-losing enteropathy is confirmed by the elevated 24-hour stool alpha-1 antitrypsin clearance.

MANAGEMENT

Low-fat diet associated with supplementary medium-chain triglycerides is the cornerstone of primary intestinal lymphangiectasia medical management.[66] It is likely that the absence of fat in the diet prevents engorgement of the intestinal lymphatics with chyle, thereby preventing their rupture with its ensuing protein and T-cell loss. Medium-chain triglycerides are directly absorbed into the portal venous circulation and thus provide nutrient fat avoiding lacteal engorgement. Other inconsistently effective treatments have been proposed for primary intestinal lymphangiectasia patients, such as antiplasmin, octreotide, and corticosteroids. Surgical small bowel resection is useful in the rare cases with segmental and localized intestinal lymphangiectasia.[158]

Other Causes of Protein-Losing Enteropathy

Congenital disorders of glycosylation and Fontan surgery to correct univentricular hearts can also cause protein-losing enteropathy. Bode and coworkers hypothesized that protein-losing enteropathy develops when genetic insufficiencies collide with simultaneous or sequential environmental insults; they found the loss of heparan sulfate proteoglycans specifically from the basolateral surface of intestinal epithelial cells of subjects with protein-losing enteropathy, suggesting a direct link to protein leakage.[16] Heparan sulfate is a glycosaminoglycan. Congenital heparan sulfate deficiency is an extremely rare disorder with severe albumin loss from the gastrointestinal tract presenting within the first week of life.

Congenital disorders of glycosylation are caused by defects in protein N-glycosylation. Congenital disorders of glycosylation are usually associated with mental and psychomotor retardation, but some forms cause coagulopathy, hypoglycemia, and liver fibrosis without neurologic involvement.[64] Westphal reported protein-losing enteropathy in a patient with a congenital disorder of glycosylation who showed reduced heparan sulfate accumulation in the enterocytes.[162]

DISORDERS OF FAT ABSORPTION

Hypobetalipoproteinemia and Abetalipoproteinemia

Hypobetalipoproteinemia is an autosomal dominant disorder characterized by decreased or absent plasma concentrations of apolipoprotein (apo)-B-containing lipoproteins and low-density lipoprotein (LDL) cholesterol.[134] In heterozygous individuals, the disorder is usually clinically silent, because the concentrations of apo-B and LDL cholesterol are 25% to 50% of normal, whereas homozygous individuals have extremely low levels.

In patients with the severe form of homozygous hypobetalipoproteinemia, there is complete absence of beta-lipoproteins, so they present clinically with fat malabsorption, acanthocytosis, retinitis pigmentosa, and neuromuscular degeneration.[87] Homozygous patients are clinically indistinguishable from patients with abetalipoproteinemia, which is an autosomal recessive condition of the apo-B deficiency state.[87] Abetalipoproteinemia (ABL) is a rare autosomal recessive disorder characterized by fat malabsorption, acanthocytosis, and hypocholesterolemia in infancy. Later in life, deficiency of fat-soluble vitamins is associated with development of atypical retinitis pigmentosa, coagulopathy, posterior column neuropathy, and myopathy. ABL results from mutations in the gene encoding the large subunit of microsomal triglyceride transfer protein (MTP). To date at least 33 MTP mutations have been identified in 43 patients with ABL.[166] Management strategies include a low-fat diet and fat-soluble vitamin supplementation.[160]

Chylomicron Retention Disease

Chylomicron retention disease, also known as *Anderson disease*,[160] is an autosomal recessive disorder of lipoprotein assembly[13] that is characterized by hypocholesterolemia, fat malabsorption, and failure to thrive. As a result of mutations in the large polypeptide subunit of microsomal triglyceride transfer protein,[13] enterocytes fail to secrete chylomicrons across the basolateral membrane.[160] It is not unusual to diagnose chylomicron retention disease in neonates who present with diarrhea, but case reports have cited delayed diagnosis in adolescents who present with vitamin E deficiency. Clinically, the presentation is similar to that of hypobetalipoproteinemia and abetalipoproteinemia, but retinitis pigmentosa and neuromuscular manifestations are less severe.[160] Vacuolated enterocytes that stain strongly with oil red[13] indicate the presence of fat within the enterocytes. On electron microscopy, lipid-laden enterocytes are seen.[13] Treatment centers on a low-fat diet and fat-soluble vitamin supplementation.[160]

Primary Bile Acid Malabsorption

Alterations in bile acid metabolism and in the enterohepatic circulation are often associated with chronic diarrhea and should be considered when more common causes of chronic diarrhea have been excluded. Bile acid diarrhea most often occurs in disease or resection of the terminal ileum, in which there is increased exposure of the colonic mucosa to bile salts with consequent activation of fluid and electrolyte secretion. Congenital or acquired defects in the enterohepatic circulation of bile acids also may lead to diarrhea.[120]

Enterohepatic circulation of bile is the primary mechanism by which the body reabsorbs 98% of the bile[94] that is reused as bile salts, and a disruption in this pathway leads to diarrhea, steatorrhea, and decreased blood cholesterol levels.[104] Primary bile acid malabsorption is an idiopathic disorder that has been linked to a missense mutation in the sodium-bile acid cotransporter gene, SCL10A2.[95,104] The diarrhea is exacerbated with the addition of dietary fats, and a remarkable improvement is noted on a trial of cholestyramine and a low-fat diet. Bile acid absorption by the ileum may be measured by using the bile acid analogue 75 Se-homocholic acid taurine test.

Akobeng and associates[2] reported an inborn error in bile acid synthesis presenting as malabsorption leading to rickets. Deficiency of 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase (3β-HSDH), the enzyme that catalyses the second reaction in the principal pathway for the synthesis of bile acids, has been reported to present with prolonged neonatal jaundice with the biopsy features of neonatal hepatitis. It has also been shown to present between the ages of 4 and 46 months with jaundice, hepatosplenomegaly, and steatorrhea (a clinical picture resembling progressive familial intrahepatic cholestasis).[2]

DISORDERS OF ELECTROLYTE ABSORPTION

Congenital Chloride Diarrhea

Congenital chloride diarrhea[160] is the most common cause of congenital secretory diarrhea with intact mucosal histopathology.[57] It is transmitted in an autosomal recessive manner,[58] and it is characterized by the passage of severe voluminous watery diarrhea that is rich in chloride. It is being recognized with increasing frequency. After an initial report on 45 cases by Hartikainen-Sorri in 1980,[53] more than 250 cases have been reported in the literature, of which greater than 50% have been reported from Finland alone. This disease is uniformly fatal without treatment. Although long-term prognosis is uncertain, survival is possible with adequate treatment.[53]

INCIDENCE

Congenital chloride diarrhea is estimated to occur at a higher frequency in Finland (1 in 20,000), Poland, and the Arab lands (1 in 32,000).[57,160]

MOLECULAR PATHOPHYSIOLOGY

Congenital chloride diarrhea is due to mutations in the intestinal Cl^- $HCO3^-$exchange (SLC26A3) which results in sodium chloride and fluid depletion leading to hypochloremic and hypokalemic metabolic alkalosis. Chloride is absorbed predominantly along the entire length of the colon and terminal ileum.[160] SLC26A3 is the transport carrier that functions to absorb chloride in exchange for $HCO3^-$. The chloride ion is absorbed as NaCl, coupled with the sodium ion provided by the Na^+/H^+ exchanger (NHE) (Fig. 47-3),

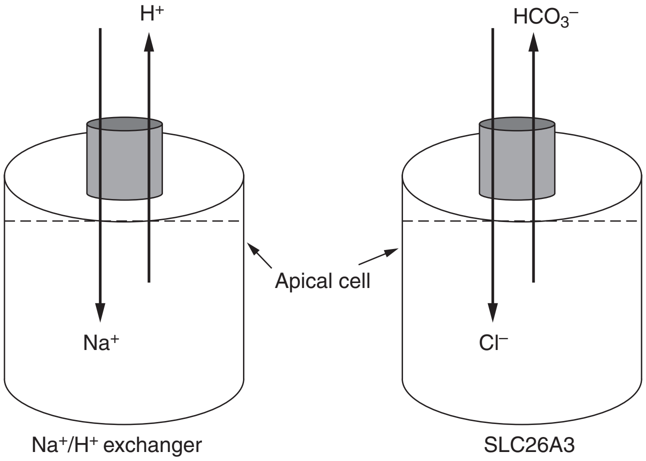

Figure 47–3. Sodium (Na^+) and chloride (Cl^-) absorption across a normal enterocyte. Sodium absorption is via a sodium hydrogen (Na^+H^+) exchanger, and chloride absorption is through the solute carrier (SLC26A3).

which is deficient in patients with congenital sodium diarrhea (see later). However, the amount of chloride secreted into the bowel is not different from the amount secreted in normal individuals; rather, the absorption is faulty at the level of the colon and ileum.[1]

CLINICAL FEATURES

Congenital chloride diarrhea is characterized by profuse watery diarrhea beginning in the immediate neonatal period. The stool has a high chloride concentration, which persists despite fasting.[1] Absence of the passage of meconium is noted, which could be explained by severe intrauterine diarrhea.[58] Wedenoja and colleagues reported a high incidence of mild chronic kidney disease in 35 other patients with congenital chloride diarrhea.[161] The main feature of the renal injury was nephrocalcinosis, without hypercalciuria or nephrolithiasis with small sized kidneys and commensurately reduced glomerular filtration rates. This suggests that diarrhea-related sodium chloride and volume depletion, the first signs of nonoptimal salt substitution, promote urine supersaturation and crystal precipitation.[161]

LABORATORY INVESTIGATION

Affected infants have watery bowel movements with high fecal chloride concentration (greater than 90 mmol/L).[57] Patients are hypokalemic, with low fecal bicarbonate concentrations.[160]

PRENATAL DIAGNOSIS

There is at present no definitive prenatal diagnosis for this condition, but a high index of suspicion must be maintained if there is a positive family history. Polyhydramnios is noted on the prenatal ultrasound,[47,77,88,109,114] and these pregnancies usually result in premature delivery. Poor visualization of the gastrointestinal canal by amniofetography, elevated amniotic fluid bilirubin levels in the absence of Rh immunization, and high amniotic fluid α-fetoprotein levels have been suggested as being indicative of congenital chloride diarrhea, but should be interpreted in the context of the clinical findings.[53,88,138]

TREATMENT
